The names Golgi body, etc., are sometimes used with the secondary implication that these objects are always self-reproducing cellular constituents, so that all the bodies called by these names in any one animal are derived by division, like chromosomes, from those present in the fertilized egg. A review of the evidence for this opinion will show that it is very slender. It is true that lipide-containing globules of the kind often called 'dictyosomes' sometimes become constricted across, and Hirschler[7] has claimed to trace the continuity of the 'Golgi apparatus' through the cleavage-stages of the egg of *Limnaea*; but it would be extremely difficult to prove that all the various bodies called by the name of Golgi are self-reproducing. It seems more likely that many of them arise in the cytoplasm without connexion with any pre-existent similar object.

A particularly strong reason why the name of Golgi should not be used is that the Italian neurologist described his 'apparatus' in the nerve-cell of vertebrates, and this is, of all cells, the one in which the real nature of the object named after him is most uncertain. He described a network with *plaquettes* distributed on it, both the net and the rims of the *plaquettes* appearing dark by his silver technique[8]. The representatives in life of the *plaquettes* appear to be the colourless vacuoles or 'spheroids' that have been studied particularly by Thomas[9]. No agreement has been reached as to the precursor, in life, of the net. Perhaps it is formed largely by the impregnation of mitochondria with osmium hydroxide or silver. Perhaps it is largely an artefact. Adamstone and Taylor[10] have described "what appears to be an intricate reticulum" in the living cytoplasm of the spinal ganglion-cells of the rat. They say that the refractive index of the reticulum is so nearly the same as that of the surrounding cytoplasm that it is often very difficult to distinguish between the two. A careful study of their photomicrographs does not convince one of the existence of a network; but the object that they regard as reticular is seen to be bright by positive phase contrast, and therefore of somewhat lower refractive index than the ground cytoplasm. If in fact a *bright* network exists in the living cell, it must be something very different from the so-called Golgi apparatus or 'lepidosomes' of the spermatocytes of the snail, for example, for these are bodies of entirely different form and are without exception the *darkest* and most evident objects seen in the living cell when it is examined by positive phase-contrast microscopy. It would be very different also from the lipoidal droplets or granules (lipochondria) that so often represent in life what is called the 'Golgi apparatus' in an osmium or silver preparation.

From time to time the question is posed by colleagues and research pupils, about an object blackened by the classical Golgi techniques, "Is this a Golgi body?" I suggest that the proper answer would be, "I do not think that your question has a meaning. It is framed in terms of an improbable hypothesis".

It is, I hope, almost unnecessary to say that no disrespect is intended to the name of Golgi, whose contributions to neurology constitute his proper memorial.

PORPHYRIN A AND OTHER PORPHYRINS FROM HEART MUSCLE

By DR. R. LEMBERG, F.R.S.

Institute of Medical Research, The Royal North Shore Hospital, Sydney, Australia

THE problem of the chemical constitution of the prosthetic group of cytochrome oxidase and cytochrome *a* was neglected for many years until it was attacked again by Rawlinson, Hale, Rimington, Lemberg and Falk[1-6] in 1949. Recently publications, mostly of a preliminary nature, have appeared by Warburg and Gewitz[7], Granick[8], and Dannenberg and Kiese[9,10]. In this article, I propose to summarize work carried out by myself with the assistance of Miss J. Parker, Mr. W. H. Lockwood, Mr. P. Caiger and Mr. B. Bloomfield.

Whereas Warburg isolated hæmin *a*, which he calls cytohæmin, in crystalline form (in a way so far unpublished), we have chosen to isolate the porphyrin. This procedure has the advantage of facilitating separation of porphyrin *a* from protoporphyrin, derived from myoglobin and cytochrome *b*, and from other porphyrins, the presence of which the technique reveals. More important still is the sensitivity of the characteristic many-banded absorption curve of porphyrins in neutral organic solvent as criterion of homogeneity and stability. Crystallization is not a sufficient criterion of this in the porphyrin group, as has been shown, for example, by Lemberg and Parker[11], who used spectrophotometric control for a chromatographic separation of chlorocruoroporphyrin and diformyldeuteroporphyrin esters from an excellently crystallized mixture. Our procedure has the disadvantage of by-product formation during the removal of the iron. Small amounts of such artefacts were, indeed, encountered, but they can be readily detected and separated from porphyrin *a*. Moreover, they are also formed in stages of the preparation preceding the removal of iron, as the earlier conflicting results of Negelein and Roche and Bénévent show. In the hæmin, small amounts of by-products are difficult to detect, but they can be found after conversion to the porphyrins. We have, indeed, ascertained the presence of small amounts of hæmin *a* in well-crystallized protohæmin preparations from heart muscle by the isolation of porphyrin *a* which cannot arise from protohæmin.

Falk and Rimington[6] abandoned attempts to isolate porphyrin *a*, as they observed alteration by hydrochloric acid of the porphyrin shown by changes in the ratio of the four absorption bands (particularly III/IV and II/IV; for numbering of the bands see last lines of Table 1). Pure porphyrin *a* is, however, perfectly stable to 25 per cent (w/v) hydrochloric acid at room temperature, and by choosing a suitable method of isolation the substances which cause the alteration in the acid medium can be eliminated before the removal of iron and before hydrochloric acid fractionation of the porphyrins.

Preparation of porphyrin a. All the methods described so far have the following defects[12]: (1) The porphyrin *a* yields were variable and small, corresponding to 0·5–3 mgm. per kgm. of wet heart muscle. (2) The ratio of the absorption bands of the neutral porphyrin solution in organic solvents, particularly the III/IV ratio, varied (Table 1). (3) Porphyrin *a* was accompanied by variable amounts of cryptoporphyrins (see below), often exceeding that of porphyrin *a*. (4) The methods were complicated and did not lend themselves to estimation of the total porphyrin *a* derivable from heart muscle.

A practically quantitative isolation of porphyrin *a* from heart muscle in spectroscopically pure form can be achieved without previous separation of the cytochromes or hæmins and without chromatographic procedures. This consists of the following steps: (1) Extraction of the minced, washed, homogenized and centrifuged tissue by acetone–hydrochloric acid at 4° C. in a medium containing approximately 20 per cent (w/w, final concentration) of water. Previous drying of the tissue with acetone or alcohol must be avoided. (2) Freezing out at − 15° C. of fat and phospholipids from the filtrate, diluted with water to a concentration of 70 per cent (w/w) acetone. (3) Extraction of the hæmins from the filtrate by ether after dilution with aqueous hydrochloric acid, followed by removal of acetone and a troublesome emulsifying agent by careful washing with dilute hydrochloric acid containing a little ferrous sulphate. Small amounts of a white emulsion in the interface are separated by centrifugation. (4) Removal of the iron by a slightly modified ferrous acetate–hydrochloric acid procedure of Warburg and Negelein, in glacial acetic acid at 70–80° C. The whole process requires less than one minute; prolonged exposure to acetic acid, particularly at higher temperatures, must be avoided. (5) Removal of acetic acid and the emulsifying agent from the ethereal solution by washing with distilled water, centrifuging if necessary. (6) Extraction of protoporphyrin and other porphyrins by 3 per cent and 8 per cent (w/v) hydrochloric acid. (7) Extraction of porphyrin *a* by 20 per cent, 25 per cent and finally 28 per cent (w/v) hydrochloric acid. The extracts are intensely blue-green and have absorption bands at 619 and 565 mμ. The ether remains faintly yellow. The hydrochloric acid extracts can be used directly for quantitative estimation of porphyrin *a* (E(0·1%, 1 cm.) = 13 at 565 mμ). (8) Washing the hydrochloric acid extracts with ether and re-extraction of porphyrin *a* with ether after dilution with disodium hydrogen phosphate solution and neutralization with solid sodium bicarbonate. The 20 per cent and 25 per cent hydrochloric acid extracts contain 95 per cent of the porphyrin *a*, which is spectroscopically almost pure (cf. Table 1) with a III/IV ratio (2·03) far higher than that of any previous preparation. Further purification no longer alters this absorption spectrum

Table 1. RATIOS OF ABSORPTION BANDS I–III TO BAND IV

	I/IV	II/IV	III/IV	Solvent
Rawlinson and Hale	0·30	1·09	1·51	Pyridine
Lemberg and Falk	0·40	1·04	1·64	Dioxan
	0·275	1·31	1·78	Chloroform
Falk and Rimington	0·28–0·61	0·90–1·22	1·23–1·66	Pyridine
Dannenberg and Kiese	0·265	0·91	1·62	Ether
Kiese	0·223	1·04	1·75	Ether
Lemberg *et al.*				
Crude porphyrin	0·205	1·13	2·03	Ether
Pure porphyrin	0·185	1·16	2·03	Ether
	0·27	1·37	2·09	Acetone
	0·26	1·41	2·11	Chloroform

Band positions in ether: I, 648; II, 583; III, 558; IV, 517; V, 412 mμ; in chloroform: I, 646; II, 584·5; III, 563·5; IV, 520; V, 418·5 mμ significantly. The small fraction obtained from the 28 per cent hydrochloric acid fraction has a somewhat lower III/IV ratio (about 1·80). The ether and acetone solutions of porphyrin *a* have a raspberry-red colour, showing red–green dichroism only at very high dilution.

Estimation. The yield measured by using an extinction coefficient $E(0{\cdot}1\%,\ 1\ \text{cm.}) = 18$ for band III at 559 mμ in neutral ether solution is 16–18 mgm. per 1 kgm. of wet muscle tissue (0·21 kgm. dry weight). To this may have to be added 0·7 mgm. found as cryptoporphyrin *a* (see below). 200–500 gm. of tissue were usually used, but the analysis can be carried out with far smaller amounts. Sheep and pig heart gave similar, slightly smaller values.

It is interesting to compare these results with the values for concentrations of cytochromes $a + a_3$ which have been calculated by Ball[16] from spectrophotometric measurements on dispersed heart muscle preparations, or which may be calculated from similar measurements by Chance[17]. For this comparison it is assumed that porphyrin *a* is the iron-free prosthetic group of both cytochromes *a* and a_3, an assumption supported by our failure to discover any other porphyrin in significant concentration to account for either (see below). Ball finds a concentration of cytochrome oxidase (cytochrome a_3) of $4{\cdot}35 \times 10^{-6}$ gm. equivalents per kgm. of wet ox heart muscle, and a ratio of cytochrome *a* to cytochrome a_3 of 3 : 1, giving a concentration of $17{\cdot}2 \times 10^{-6}$ gm. equivalents/kgm. for total porphyrin *a*, which is in close agreement with our figures ($17{\cdot}1$–$19{\cdot}2 \times 10^{-6}$). From Chance's ratio for the concentrations $a_3 : a : c = 1 : 2 : 1{\cdot}6$ and the cytochrome *c* concentration in ox heart (about 15×10^{-6} gm. equivalents/kgm.), figures of $9{\cdot}2 \times 10^{-6}$ for cytochrome a_3 and $27{\cdot}6 \times 10^{-6}$ for total porphyrin *a* result. Both methods are indirect, and Chance's results require further assumptions on molar extinctions which are based on rather doubtful analogies. This may explain why they give higher values.

Reconversion of porphyrin a to hæmin a. The reconstituted hæmin *a* shows only one band (587 mμ) in the visible part of the spectrum, and a Soret band at 430 mμ after reduction of a slightly alkaline solution in 50 per cent pyridine with dithionite. We have not observed the appearance of a band at 558 mμ, which Warburg noticed on dithionite reduction. Since this readily occurs with cryptohæmin *p* (see below), Warburg's hæmin probably contained some of this hæmin as impurity. The ratio of the Soret band to the band at 587 mμ is remarkably low (4·5). This is also a feature of the ferrocytochrome *a* spectrum, though not of ferrocytochrome a_3. Altogether it appears that hæm *a* is far less modified in its properties by its combination with protein in cytochrome *a* than it is in the cytochrome oxidase.

Further purification. Further purification with removal of colourless impurities was carried out. (1) By extraction of fatty acids (together with a variable, usually small part of porphyrin *a*) from ether by 0·02 *M* phosphate of *p*H 6·5. Porphyrin *a* is extracted by disodium hydrogen phosphate and brought back into ether with phosphoric acid at *p*H 4. (2) By repetition of the extraction by hydrochloric acid from ether. The main part of porphyrin *a* is now extracted by 10 per cent and 15 per cent (w/v) hydrogen chloride and brought back into ether with neutralization to *p*H 4. The fact that the first fraction gives a porphyrin the ratio III/IV of which is not lower than that of the second proves the absence of cryptoporphyrins. (3) By repeated precipitation from chloroform by light petroleum or from ether by benzene. These procedures give fine precipitates which are distinctly microcrystalline under the polarization microscope. In a thin layer, solid porphyrin *a* is green in transmitted light; in a thicker layer it shows the typical metallic surface colour of porphyrins. (4) By fractional extraction of the solid porphyrin *a* with ether. This procedure is repeated until the first extracts have no lower specific extinctions than the later ones. Pure porphyrin *a* is not easily soluble in ether and the measurements are carried out in acetone.

Esterification with diazomethane causes no alteration of the absorption spectrum; but, so far, attempts to purify the ester further by chromatography or crystallization have failed.

By these methods the specific extinction coefficient ($E(0{\cdot}1\%,\ 1\ \text{cm.})$) at 558 mμ in acetone was raised to between 18·0 and 18·1 in a large number of preparations. From the specific extinctions the molecular weight can be established if the molar extinction is known. Oliver and Rawlinson[12] have measured this by copper titration as 16,900 for band III of porphyrin *a* in acetic acid. Since the influence of solvents on the extinction of this band is negligible, we can calculate the molecular weight as 935. A second calculation giving a value of 930 is based on the sum of the specific extinction coefficients of bands III and IV ($18{\cdot}1 + 9{\cdot}5 = 27{\cdot}6$), and the sum of the molar extinction coefficients of these two bands, which is surprisingly constant for a great diversity of porphyrins, and for nineteen porphyrins of rhodo-type, averages 25,350 (cf. Table 2; values of A. Stern *et al.*[13], Lemberg and Parker[11] and Granick[14]).

Our molecular-weight value is higher than those which can be calculated for the porphyrin on the basis of iron estimations of the hæmin by Granick (850) and by Warburg (780). It confirms that porphyrin *a*, in contrast to other porphyrins, contains a large fatty acid or alkyl side-chain which does not contribute to its colour.

Structure of porphyrin a. Three characteristic side-chains have now been defined in porphyrin *a*: (1) a 'rhodofying' group which is practically certain to be a formyl group; (2) a second rhodofying group in a position strongly enhancing the effect of the formyl group on the spectrum, containing an ethylenic double bond; (3) a large alkyl or, more likely, fatty acid side-chain.

Evidence for the formyl group rests on reactions of the hæmin with cysteine[1], hydroxylamine[5] and hydrazine[5], on spectroscopic evidence for the conversion of an aldoxime to a nitrile[10], and on reaction of the porphyrin with aluminium propoxide[5] and with methanolic hydrochloric acid[5,15]. Porphyrin *a* does not contain the isocyclic ring which is present in chlorophyll derivatives. The alteration of the spectrum by methanolic hydrochloric acid superficially resembles the conversion of phæoporphyrins into chloroporphyrins; but is, in fact, a methyl acetal formation, since in contrast to the opening of the isocyclic ring it is readily reversed, for example, by the action of dilute hydrochloric acid on a chloroform solution of the acetal[15].

The ethylenic double-bond nature of the second rhodofying group is supported by the spectra of the compounds obtained by the action of diazoacetic ester or hydriodic acid, followed by hydroxylamine[5]

Table 2

Porphyrins	Rhodofying groups	Ratio III/IV	$E^{\mathrm{III+IV}}_{\mathrm{mM}}$
Phæo-a_7	C_6 to $C\gamma$: —CO—O—C(OH)(CO$_2$M)—	1·18	23·2

* Negative rhodofying influence. † In chloroform ; in dioxan, 1·21 and 1·43.

and by observation on catalytic hydrogenation[7,8,10]. Lemberg and Falk[8] considered the rhodofying action of a vinyl side-chain insufficient to account for the porphyrin spectrum; but recent observations of Granick[14] on vinylphæoporphyrin a_5 show that a vinyl group in a suitable position relative to a carbonyl group can have a very strong rhodofying effect (increase of the III/IV ratio from 1·71 to 2·15), although this still would not account for the very strong red shift of the porphyrin *a* absorption bands. Porphyrin *a* also behaves abnormally in reactions with hydrobromic acid in acetic acid, and with permanganate in acetone[15]. Table 2 shows that all porphyrins with a ratio of III/IV greater than 2 and a marked 'oxorhodo' type spectrum[8] (II/IV greater than 1), have two rhodofying groups on diametrically opposed pyrrole rings (in positions 2 and 6). The far lower ratio III/IV of chloroporphyrin e_4 is due to the presence of a methyl group on the methine bridge which lowers band III. Presence of two rhodofying groups on vicinal pyrrole rings, on the contrary, causes an ætiotype spectrum (ratio III/IV less than 1), independent of the relative positions of the groups on these pyrrole rings, for example, 2–4 in diformyldeuteroporphyrin, or 3–6 in phæoporphyrin *b*. Present evidence thus indicates the 2–6 position of the two rhodofying groups. Their presence on the same pyrrole ring, as assumed by Warburg, cannot be ruled out. It is conceivable that two such groups on one pyrrole ring may have the same effect as on opposite pyrrole rings, but there is no experimental evidence for this.

The long-chain lipophilic group of porphyrin *a* causing the large molecular weight is not present as an ester group; no saponification occurs under conditions under which phytol is removed from chlorophyll[15]. This nature of porphyrin *a* explains the special difficulties of its preparation, and it must confer on cytochrome oxidase and cytochrome *a* a lipoprotein character. This is of particular interest because of the well-known close association of the respiratory cytochromes and lipids in mitochondria. Nature has achieved the conversion of a porphyrin to a lipid material in two different ways: by conversion into a fatty acid by C—C combination with a long fatty acid side-chain, probably by a semi-independent synthesis, for the respiratory enzymes of cytochrome *a* type; and by esterification of a carboxyl with a large alcohol molecule for the chlorophylls.

Cryptoporphyrin. Porphyrin *a* is always accompanied by another porphyrin, the hæmin of which in pyridine-dithionite gives absorption bands at 582 and 533 mμ. This porphyrin was first obtained by Negelein[16] from pigeon breast muscle, but later considered as an artefact derived from protohæmin. Probably for this reason it has been neglected by later workers. It is found in the 8 per cent hydrochloric acid fraction of the Willstätter separation, and is best separated from accompanying protoporphyrin by 9 per cent (w/v) sulphuric acid. We have isolated cryptoporphyrin *a* from ox heart muscle from which the major part of the protohæm compounds, myoglobin, had been removed by saline extraction, and have obtained a crystalline methyl ester by esterification with diazomethane followed by alumina chromatography, by crystallization from ether at − 15° C., and by recrystallization from chloroform-ether. A similar porphyrin was obtained under certain conditions as crystalline methyl ester in a similar way from hæmoglobin and saline extracts of heart muscle, for example, when acetone was incompletely removed prior to treatment with ferrous acetate–hydrochloric acid. Table 3 shows that this porphyrin, which we call cryptoporphyrin *p*, differs from cryptoporphyrin *a*. Hydroxylamine shifts the absorption band of the cryptohæmochromogen *a* 20 mμ towards the blue, indicating that cryptoporphyrin *a*, like porphyrin *a*, is a formyl porphyrin, whereas the cryptoporphyrin *p* hæmochromogen behaves quite differently. The specific extinction coefficients of a solution of cryptoporphyrin *a* in chloroform are: $E(0{\cdot}1\%, 1\ \mathrm{cm.}) = 19{\cdot}45$ at 559 mμ and 15·7 at 519 mμ. From $E_{\mathrm{III+IV}} = 35{\cdot}15$ a molecular weight of 700 (for the free porphyrin) is calculated. The yield of cryptoporphyrin *a* was established by spectrophotometric measurements in the crude mixture with protoporphyrin as about 0·7 mgm. per kgm. of wet heart muscle. Under

Table 3. CRYPTOPORPHYRINS

	Cryptoporphyrin *a*		Cryptoporphyrin *p*

	519	1·0	514·5	1·0
	421	13·3	415	13·6
Absorption spectrum in 10 per cent hydrochloric acid	λ in mμ 613, 563·5		608·5, 559·5	
Crystal form	Diamonds with 24° sharp angle		Almost rectangular elongated plates	
Melting point	259–260°		248–249°	
Hæmochrome	λ in mμ 582, 533		577, (556*), 525	
+ hydroxylamine	λ in mμ 562, 533		610, 567	

* This band increases on standing with dithionite

conditions in which cryptoporphyrin *p* is not formed from protohæm, the yield is little altered by previous saline washings of heart muscle, indicating that cryptoporphyrin *a* is derived from hæm *a*, not from protohæm. Moreover, cryptoporphyrin *a* is obtained in the same yield from the ether fraction containing hæmin *a* from which protohæmin has been removed by washing with pyridine–hydrochloric acid according to Rawlinson and Hale. The molecular weight of cryptoporphyrin *a*, lower than that of porphyrin *a*, can be due either to the possible impurity of porphyrin *a*, or to cryptoporphyrin *a* having substantially higher molar extinctions for bands III and IV than porphyrin *a*. It will still have to be decided whether cryptoporphyrin *a* is an artefact derived from porphyrin *a* or is present as cryptohæm *a* in heart muscle; in any event it is present in too small a concentration to be the prosthetic group of either cytochrome oxidase or cytochrome *a*. This supports the assumption made above that porphyrin *a* is the prosthetic group of both cytochrome *a* and cytochrome oxidase.

This research has been supported by grants from the National Health and Medical Research Council of Australia.

MECHANISM OF PHAGE ACTION

By MARGERIS A. JESAITIS and WALTHER F. GOEBEL

Laboratories, Rockefeller Institute for Medical Research, New York 21, N.Y.

THE processes involved in the initiation of viral synthesis when phage and susceptible micro-organism encounter one another are by no means understood, despite the effort which has been expended these past few years to unravel this complex problem. The affinity between the bacteriophages and their hosts is highly specific and appears to be dependent upon the presence of receptor sites on the surface of both the virus particle and the bacterial cell alike. In the case of the dysentery bacillus Phase II *Sh. sonnei* and the various *T* coli-dysentery phages which attack this micro-organism, it has been suggested that it is the type-specific somatic antigen which serves as the viral receptor[1]. This suggestion has some basis in fact, for it has been shown that *in vitro* the chemically purified antigen derived from this bacillus has the ability to inactivate all of the *T* phages to which this micro-organism is susceptible[2]. The mode of action of this substance upon the virus is not known; it is our belief, however, that the antigen, as it occurs *in situ*, takes an important role in the initiation of the infectious process.

Recent studies on the interaction of isotopically labelled bacteriophage and *E. coli B* indicate that the virus particle is disintegrated when it comes in contact with the susceptible cell[3,4]. The purpose of the present investigation is to establish whether a similar event takes place when phage suffers inactivation *in vitro* by the somatic antigen of Phase II *Sh. sonnei*.

The wild type of the T_4 phage and the lipocarbohydrate moiety of the Phase II antigenic complex were chosen for study. A culture of *E. coli B* was grown in a synthetic medium and infected in the logarithmic phase with the T_4 phage. After lysis had occurred, the virus was concentrated by spinning in a Sharples centrifuge. It was purified by treatment with deoxyribonuclease; after filtration through a Berkefeld candle, the virus was finally obtained by differential centrifugation. Suspensions containing 10^{12} viral particles per ml. were thus secured. The bacterial lipocarbohydrate was prepared by dissociating in 90 per cent phenol the somatic antigen of Phase II *Sh. sonnei*, derived from formol-killed micro-organisms[5,6]. Sterile solutions of this material were prepared by wetting the lyophylized lipocarbohydrate with a small amount of 70 per cent ethanol (0·2 ml./10 mgm.) prior to dissolving it in sterile buffer.

If a solution of the specific bacterial lipocarbohydrate is now added to a dilute suspension of T_4 phage at 37° C. (10^{10} particles/ml. or less) no apparent changes can be detected apart from inactivation of the virus, as determined by infectivity titre. If, however, a highly concentrated phage suspension is mixed with the lipocarbohydrate, a marked and rapid

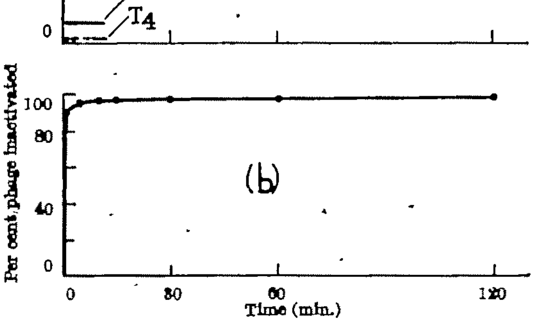

Fig. 1. Effect of the lipocarbohydrate (200 γ/ml.) on T_4 phage ($1·85 \times 10^{11}$ particles/ml.) in 0·1 *M* sodium phosphate buffer at *p*H 6·8 and at 37° C. (*a*) Change in viscosity of T_4 suspension after addition of lipocarbohydrate; the specific viscosities of the lipocarbohydrate solution (*LC*) and of the phage (T_4) suspension alone are at the bottom of the diagram. (*b*) Rate of inactivation of the virus as measured by infectivity titration

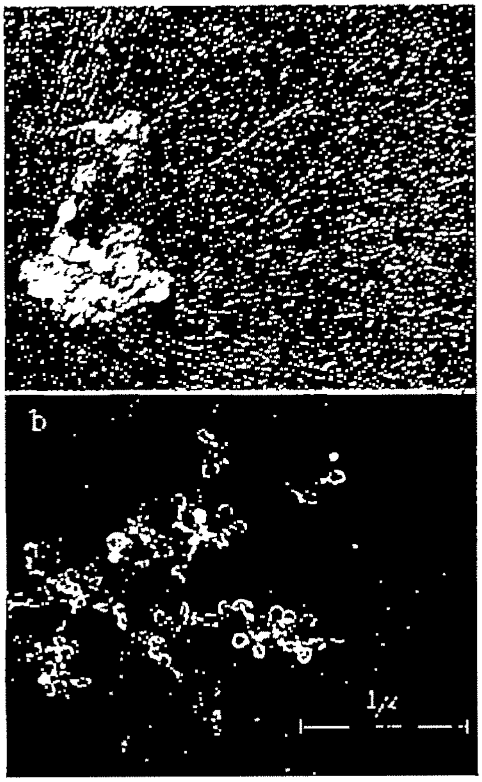

Fig. 2. Electron micrographs of T_4 phage after treatment with lipocarbohydrate. (*a*) Lysed virus with surrounding filaments; preparation obtained by drying a droplet of the solution on 'Formvar'-coated grid; shadowed with gold and chromium (× 24,000). (*b*) T_4 ghosts after lysis of the virus with lipocarbohydrate; preparation dehydrated by critical point method, shadowed with chromium (× 24,000). The micrographs were taken through the courtesy of Dr. Keith R. Porter, of the Rockefeller Institute

increase in the viscosity of the solution occurs. This change in viscosity is paralleled by inactivation of the phage (Fig. 1). Since the specific viscosity of the phage suspension and that of the lipocarbohydrate solution are low, it is evident that the marked increase in viscosity which occurs when the two substances are mixed can be attributed to the release of some new material in the solution.

Indeed, if one examines a desiccated droplet of the phage–lipocarbohydrate mixture in the electron microscope, it can be seen that the solution now contains a large number of phage ghosts and many filaments (Fig. 2*a*). Some scattered granular material can also be observed in the background of the electron micrograph. The clearly discernible filaments appear to be uniform in thickness and to extend over a distance of several microns; their diameter can be estimated as 50–100 A. A group of the lysed phage particles can be seen in the left corner of the electron micrograph; it will be noted that only a few intact phage particles remain. The structure of the empty phage membranes themselves can be more distinctly observed when the specimen for microscopy is prepared by the critical point method[7]. It is evident from the second micrograph (Fig. 2*b*) that the empty membranes retain for the most part the shape of the original phage particle; their tails, however, appear to be shorter than those of non-lysed phage. It will also be observed that here the filaments are coiled and twisted in a tri-dimensional pattern. Since the lipocarbohydrate itself appears on electron micrographs in the form of tiny granules 50–100 A. in diameter, it is very probable that the filaments originate from the phage particles themselves.

An investigation, not yet completed, is being made of the products which result from the interaction of the virus and the specific lipocarbohydrate. At the present time it may be stated that at least part of the phage nucleic acid is liberated in free form. It has been found that, on centrifuging the phage–lipocarbohydrate mixture, some 40 per cent of the total nucleic acid is carried down with the rapidly sedimenting protein components of the phage. The liberated nucleic acid not only sediments more slowly, but it also forms a separate and sharp boundary which has a sedimentation constant of $7 \cdot 0 \times 10^{-13}$. On electrophoresis this substance gave a single peak having a mobility of $-17 \cdot 4 \times 10^{-5}$ cm.^{2} volt^{-1} sec.$^{-1}$, calculated from the ascending pattern. The measurements were made in phosphate buffer at *p*H 6·8 and of ionic strength 0·1.

It can be observed, moreover, that on treating the lysed phage–lipocarbohydrate mixture with deoxyribonuclease the solution rapidly loses its viscosity. Apparently both the bound and free nucleic acid are hydrolysed by the enzyme, for a characteristic boundary can no longer be observed when the mixture is examined in the ultracentrifuge.

The lipocarbohydrate is apparently not destroyed when it reacts with the virus, since there is no liberation of dialysable saccharides. It has been found, on the other hand, that a given amount of lipocarbohydrate will inactivate only a certain number of phage particles; approximately 2×10^{-16} gm. of lipocarbohydrate is required to inactivate one viral particle. This fact indicates that the lipocarbohydrate is removed from the reaction mixture and in all probability is bound by the components of the lysed phage. Electrolytes are essential for the consummation of the reaction, for if the salt concentration is 0·02 *M* or less the phage remains unaffected. The reaction proceeds rapidly between *p*H 6·0 and 9·0, but not outside this range. Finally, it may be stated that, if the lipocarbohydrate is extracted with 70 per cent ethanol, it will no longer cause lysis of the phage. During this process a small amount of lipid is removed. This material in itself is without activity; but if it is again mixed with the extracted and inactive lipocarbohydrate the virolytic activity of the latter is fully restored. In this respect, the unidentified lipid can be considered as serving in the capacity of co-factor. Its action is not specific, however, as it has been found that certain saturated fatty acids such as myristic, palmitic and stearic acids will likewise fulfil this function.

In conclusion, it may be stated that, when the specific lipocarbohydrate of Phase II *Sh. sonnei* comes in contact with the coli-dysentery phage T_4, there is a prompt release of the content of the viral membrane. Since the lipocarbohydrate is a component of the antigenic complex which is present on the cell surface of the Phase II bacillus, it is our belief that it is this substance which triggers the release of genetically active material from the phage when the virus encounters the living host.

Growth of Excised Fern Leaves in Sterile Culture

THE techniques of sterile culture have for some years been successfully applied to the elucidation of problems of the developmental physiology of roots and shoots[1], both of which possess meristems with indeterminate growth. More recently, the same techniques have been applied to a study of flowers and fruits[2], determinate organs which undergo only a limited meristematic development. Although detached leaves have been kept alive for varying periods of time[3], and leaf disks and small whole leaves have been reported to undergo limited growth in culture[4], so far as we are aware there has been no systematic attempt to use sterile culture techniques in the study of developmental problems of leaves. Because of its prolonged but limited terminal embryogeny, the fern leaf seemed to afford favourable material for such a study.

The fern used for these studies was *Osmunda cinnamomea* L., the cinnamon fern. This fern has a compact apical bud containing 60–80 immature leaves, one-quarter of which will be utilized in each of the four successive growing seasons[5]. Representative leaves from each of the inner three annual sets have been used in these experiments and have been designated for convenience sets I, II and III, I being the youngest. At the time of excision, set III leaves averaged 12·0 mm. in length, set II averaged 1·8 mm. in length, and set I less than 1 mm. in length.

The compactness of the bud facilitates sterilization since the inner leaves are already free of micro-organisms, and a surface sterilization of the whole bud in a 7 per cent solution of calcium hypochlorite does not injure these leaves. The excised leaves were grown for the most part on two media solidified with 0·8 per cent agar. The simpler of the two media contained Knop's solution with trace elements, 2 per cent sucrose, and a mixture of ten B vitamins. The more complex medium contained in addition to these constituents naphthalene-acetic acid (0·05 mgm./lit.), autoclaved coconut milk (15 per cent), and a mixture of eighteen amino-acids.

Excised leaves of diverse sizes and ages undergo growth and development in sterile culture, as indicated by increases of height, fresh weight and dry weight, and by the progressive appearance of new morphological features. The nature of the final product of leaf development *in vitro* is determined both by the size and age of the primordium at the time of excision and by the conditions of culture.

As an example of such development the growth of leaves of set III may be considered. At the time of excision these consisted of a broad basal portion at the tip of which was a tiny meristematic hook representing the initial stage of the crozier. Pinna formation was just beginning in the largest of the set III leaves. These leaves reached maturity in 8–10 weeks, undergoing, in one experiment, approximately a five-fold increase in height, a fourteen-fold increase in fresh weight, and an eight-fold increase in dry weight. At maturity the leaves possessed a rachis bearing about thirteen pairs of pinnatifid pinnæ. The appearance of new morphological features indicates that there had been organized meristematic growth in culture. This is in contrast to earlier reports of growth entirely by increase of cell size in cultured leaf disks[4].

Early increase in height of excised leaves was due to enlargement of the basal portion. Very soon, however, the crozier began to develop and, eventually, at about the time that growth of the base was complete, it uncoiled, setting off successive pairs of pinnæ. This development of excised leaves closely resembles that of normal leaves on the plant with several notable differences. The height of the largest cultured leaves was approximately one-tenth that of typical fronds growing under natural conditions, and cultured leaves had only one-third to one half the number of pinnæ. Excised leaves of set III in culture reached maturity in 8–10 weeks, whereas comparable leaves on the plant would have required slightly more than a year, including a period of dormancy, to complete their development[5]. The extent to which the smaller size of cultured leaves may be related to their precocious development rather than directly to nutritional or other factors is not yet clear.

Excised leaves of set II and set I also underwent considerable development in culture, giving rise to fully mature fronds. It should be noted that the excised primordia of sets I and II gave rise to mature leaves which were smaller than those produced by set III explants (see accompanying table). However, the increase in size, relative to the original measurements, was many times greater in the younger leaves. The development of leaves of sets I and II was profoundly affected by the composition of the medium, not only in size but also in structure. On the more complex medium the mature leaves produced were both taller and heavier, and even the smallest primordia cultured produced tiny pinnate fronds. Leaves grown on the simpler medium, on the other hand, not only were smaller, but also showed a morphological reduction, being of a relatively simple type. In contrast to this, leaves of set III grown on the complex medium were somewhat heavier than those grown on the simpler medium, but showed no significant increase in height or in morphological development.

GROWTH OF EXCISED LEAVES OF SETS I, II AND III ON COMPLEX MEDIUM

Set	Average initial: Height mm.	Fresh wt. mgm.	Dry wt. mgm.	Average final: Height mm.	Fresh wt. mgm.	Dry wt. mgm.	No. of pinna pairs
III	12·0	30·00	7·63	77·3	463·33	69·20	13·5
II	1·8	0·71	0·27	33·0	104·75	24·93	10·5
I	<1·0	—	0·08	11·0	22·66	6·52	5·3

Leaves of sets I, II and III were grown in the dark on both the simple and the complex medium. Older leaves developed more extensively, but in no case did any leaf reach maturity during the course of experiments in which all leaves in the light matured. Prior to uncoiling, however, the croziers of dark-grown leaves became considerably larger than those of leaves in the light, and contained a larger number of pinnæ. The uncoiling phase of development, however, was retarded, and in many cases did not occur at all.

The experiments reported in this communication have shown that it is possible to grow excised fern leaves in sterile culture from the primordial stage to maturity, under controlled nutritional conditions.

This technique makes possible a new approach to the problems of leaf physiology and development. At the same time it has been demonstrated that the complex pattern of leaf development in ferns, including apical growth of a determinate nature and the formation of lateral organs in regular sequence, is inherent in the leaf itself, although it may be modified by stimuli external to the leaf.

A detailed account of these experiments will be published elsewhere.

Action of Irradiated Cytoplasm on Untreated Chromosomes of the Silkworm

The possibility that irradiated cytoplasm may produce genetical effects in untreated chromosomes has been re-tested recently by Bonnier *et al.*[1], with inconclusive results, except for the case of gynandromorphs. The time interval between irradiation of the cytoplasm and entrance of the sperm would be expected to be a major factor in experiments of this nature. Recovery and photo-reactivation of irradiated cytoplasm have been observed by Henshaw[2] and Harold *et al.*[3] for the egg of the sea-urchin. This suggests that a possible mutagenic power of irradiated cytoplasm may also be lost if the interval between irradiation and fertilization is too long.

With this point in mind, I have tried to induce genetical effects in untreated silkworm spermatozoa which were introduced into irradiated eggs within two or four hours after irradiation. The mutant genes used were *pe* and *re*. Both are located on chromosome *V*, at 0·0 and 31·7 respectively. Both of them control the colour of the egg, or more accurately the colour of the serosa, which is a character of the F_1 generation. Whereas the normal colour is black, *pe*/*pe* eggs are white, and *re*/*re* eggs, red. Eggs homozygous for both mutants are also white.

Females of genotype *pe re*/*pe re* were irradiated with a dose of 80 kVp., 4 m.amp. at a target distance of 15·5 cm. and without filter. They were then mated to wild-type males. In order to shorten the interval between irradiation and egg-laying, the females were, previous to irradiation, kept at about 10° C. for 12 hr., and the period within which mating was possible was restricted to 2 or 4 hr. Control females were cooled in the same way. Eggs laid by control and treated females were classified as to colour. The normal colour of + +/*pe re* eggs is black. Red or white eggs, or eggs which are mosaic for black and red or black and white, are found very occasionally in the controls. They are frequent in the progeny of untreated *pe re*/*pe re* females and irradiated wild-type males[4]. Their occurrence in the progeny of untreated wild-type males and irradiated *pe re*/*pe re* females in excess of the control frequency would show an effect of the irradiated cytoplasm on the introduced paternal chromosomes. Since it is difficult to distinguish white eggs from unfertilized ones and red eggs from dead ones, classification for non-mosaic eggs was done at a later stage than for mosaic ones, and is less reliable. But as mosaics form the bulk of the aberrants, this does not materially affect the result.

The results from three experiments are summarized in the accompanying table. In spite of the unusually high frequency of aberrants in the second control test, the effect of the irradiated cytoplasm is clear in all the experiments. The magnitude of the difference between treated and control series depends on the X-ray dose (Exps. 1 and 2) and, to a greater extent, on the time interval between irradiation and fertilization (Exps. 1 and 3). The frequency of aberrants in Exp. 3, namely, 0·52 per cent, is comparable with the effect of 1,500 r. when applied directly to mature spermatozoa. With direct treatment of sperm also, the majority of the aberrants are mosaics[5].

The origin and production of mosaic eggs in the silkworm have been described by Tazima[6], who attributes mosaicism to the occurrence of deficiencies at the marked loci. This point will be further discussed in a forthcoming publication on the induction of mosaicism by nitrogen mustard. The fact that the ratio between white and red aberrants (50/29 = 1·72) is in good agreement with that found after direct treatment with nitrogen mustard is taken as support for the assumption that the observed effects

are due to chromosomal deficiencies or other chromosomal aberrations.

Other possibilities which have to be considered are double fertilization, or abnormal fertilization between egg nucleus and a polar body nucleus. Indeed, cases of mosaicism due to one of these causes have been reported[6]. However, dispermic merogony cannot account for mosaics in the progeny of wild-type males, and areas arising from the fusion of two maternal egg nuclei would be genetically *pe re/pe re*, that is, white, so that at least the red mosaics cannot be due to this cause.

Somatic crossing-over should also be considered. In this case, the red areas would be due to double crossing-over, and this would mean an unusually high amount of double crossing-over.

Whatever the origin of the mosaics, it must be genetical in nature, and the present results thus show that irradiated cytoplasm may have a strong effect on untreated chromosomes.

I wish to thank Dr. C. Auerbach for her valuable criticisms and for her kindness in reading the original manuscript. Thanks are also due to Dr. Y. Tazima, of the Silk Science Research Institute, and Prof. K. Murati, of this Laboratory, for advice and assistance in completing this work.

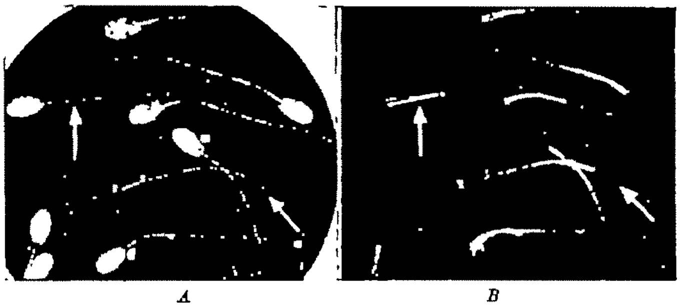
Dark-Ground Illumination of Ram Spermatozoa

THE tails of spermatozoa were generally thought to be radially symmetrical; although Randall and Friedlaender[1] have shown that the tails of ram spermatozoa are elliptical and slightly flattened, this may have been due to the drastic treatment necessary for inspection by electron microscopy. Challice[2], however, has produced more convincing evidence in the case of the mouse. He cut transverse sections of the spermatozoa tails, which, examined with an electron microscope, showed them to consist of a core of fibrils flanked by two ridges each composed of a single lateral fibril.

Departures of the tails and midpieces of spermatozoa from radial symmetry can be illustrated by using dark-ground illumination. The accompanying photographs are of the same preparation of ram spermatozoa treated with a nigrosin and eosin differential live/dead stain, one by dark-ground illumination and one by transmitted light. The midpieces of ram spermatozoa do not have the appearance one would expect if they were radially symmetrical. When viewed by dark-ground illumination, the lines of light representing the outline of the midpiece appear to cross, and when the same preparation is examined closely by transmitted light, the midpiece is seen to be slightly thinner at the cross-over point, an observation which may have been overlooked by previous workers.



(*A*) Ram spermatozoa, treated with nigrosin and eosin stain, photographed by transmitted light. (*B*) The same preparation photographed by dark-ground illumination. In each photograph the arrow on the left points to one of the twisted mid-pieces, and the other arrow indicates the only stained spermatozoon in the field. (× 570)

There are several possible explanations of this; one of the most reasonable seems to be that the midpiece is elliptical in cross-section, and has become twisted. Randall and Friedlaender have confirmed their observations, on the main piece of the tail, by its appearance when twisted. Alternatively, the ram spermatozoa may have a similar structure to those of the mouse (as regards midpiece and tail) and the midpieces have become twisted. Challice, in Plate I, Fig. 1 of his paper[2], appears to have photographed a twist in the mouse spermatozoon tail. We have not been able to detect this by dark-ground illumination in mouse material, possibly because the tail is extremely fine. Twists have also been observed in spermatozoa of the boar, and once in those of the bull.

In the preparation illustrated, the twisted midpiece is found in spermatozoa which have not taken the stain, that is, in the live spermatozoa[3]. These can also be distinguished by dark-ground illumination because the outline of the head is clear, whereas the stained spermatozoon is ill-defined.

The twist has not been observed in spermatozoa untreated with nigrosin and eosin stain, and it may therefore be an artefact. This stain is, however, not particularly toxic to spermatozoa for they remain motile in it for some time, and distortion is slight, as can be seen by comparing a nigrosin and eosin preparation with cells viewed under the phase-contrast microscope.

If lateral ridges are a general morphological feature of spermatozoa, then it would be logical to expect a twist in the midpiece or tail to provide a mechanism for the rotary helical movement of the free spermatozoa.

I wish to thank Dr. A. Walton for advice and encouragement, and Mr. A. V. Guntrip for the introduction to dark-ground illumination and for taking the photographs.

Carotene: a Rachitogenic Factor in Green-feeds

In a previous communication[1], evidence was presented indicating the presence of a rachitogenic factor in green-feeds. Experiments have shown that, for the rat on a rachitogenic ration, the bone ash response to a fixed dose of vitamin D is depressed by increasing doses of a green-feed extract in the manner indicated in Table 1.

Table 1

Group (18 rats per group)	Daily dose per rat Vitamin D* (I.U.)	 Dried grass (mgm.)†	Average ash in dry fat-free femur (per cent)
1	0 075	0	33·2
2	0·15	0	37 9
3	0·15	1·75 (1·2 μgm. carotene)	38 1
4	0·15	3·5 (2·4 „ „)	36·3
5	0·15	7·0 (4·8 „ „)	35 6
6	0·15	14·0 (9·6 „ „)	32·9
7	0·15	28·0 (19·2 „ „)	31·6

* Amount dosed in 0·1 gm. olive oil solution.
† The equivalent weight of dried grass dosed as the chloroform extract in 0·1 gm. olive oil solution.

Statistical analyses carried out on these and on the results of eight other similar trials indicated a linear relationship between response (per cent bone ash) and log dose. A method was devised whereby an approximate estimate of the potency of the rachitogenic factor in a green-feed extract or concentrate could be obtained, an arbitrary unit being provisionally defined as "the amount which, when dosed daily to the rat on the McCollum 3143 rachitogenic ration plus a daily supplement of 0·15 I.U. vitamin D, would depress the bone ash response to that normally produced by a daily supplement of 0·10 I.U. vitamin D". Thus it became possible to follow quantitatively the fate of the active principle throughout the processes involved in its isolation. By chromatographic fractionation of a petroleum ether extract of dried green oats, the rachitogenic factor was isolated and identified as carotene.

The amount of carotene in each dose of extract described in Table 1 is indicated by the figures in brackets. The results obtained by dosing increasing amounts of carotene (B.D.H., 90 per cent β – 10 per cent α) to rats receiving the McCollum 3143 ration and a daily supplement of vitamin D are presented in Table 2.

Table 2

Group (24 rats per group)	Daily dose per rat Vitamin D (I.U.)	 Carotene (μgm.)	Average ash in dry fat-free femur (per cent)
1	0·05	0	32·4
2	0·10	0	34·8
3	0·20	0	38·7
4	0·15	0·781	34·9
5	0·15	3·125	34·3
6	0·15	12·5	32·6
7	0·15	50·0	31·2
8	0·15	100·0	30 6

That vitamin A probably has a similar rachitogenic effect is seen from the results of a preliminary trial shown in Table 3.

Table 3

Group (12 rats per group)	Daily dose per rat Vitamin D (I.U.)	 Vitamin A (I.U.)	Average ash femur dry fat-free (per cent)

Analyses of green-feeds in this laboratory have indicated a carotene content as high as 840 μgm. per gm. of dry matter, so that animals grazing on such fodder have a high carotene intake—the equivalent of 1–2 million I.U. of vitamin A per day in the case of sheep, and for cattle about ten times this amount. In addition to this, an appreciable quantity of carotene appears to be synthesized by micro-organisms of the ileum and cæcum[2].

The identification of carotene as a rachitogenic factor for rats and the relatively large amounts of this substance present in green-feeds suggest that the rachitogenic effect of winter green-feed on sheep is due to the high carotene intake at a time of the year when the vitamin D status of the animal is normally low. This hypothesis is to be tested by sheep trials during the coming winter. The further possibility of a high carotene intake having other adverse effects on the health of farm animals is also being investigated.

A detailed account of this work, together with comprehensive statistical analyses carried out by Dr. A. H. Carter, of the Animal Research Station, Ruakura, will be presented elsewhere.

Tryptophane Metabolism in Rice Moth Larva (*Corcyra cephalonica* St.)

EARLIER workers[1], who observed the excretion of the tryptophane metabolites, kynurenine and xanthurenic acid, by the rat and the rabbit under conditions suggestive of vitamin B deficiency, failed, however, to realize its physiological significance. It was not until Lepkovsky *et al.*[2] isolated and identified the pigment metabolite, xanthurenic acid, from the urine of pyridoxine-deficient rats receiving extra-dietary tryptophane, that the rôle of this vitamin in the metabolism of the amino-acid was unequivocally established. Since then, a number of reports have appeared of the conversion of tryptophane to xanthurenic acid, kynurenine, hydroxykynurenine, etc., by pyridoxine-deficient rats, rabbits and dogs[1,3]. In 1945, Sarma[4] found that the rice moth larva (*Corcyra cephalonica* St.), maintained on a pyridoxine-deficient diet containing added tryptophane, excreted yellow-coloured fæces. This was about the first and only report on the rôle of pyridoxine in tryptophane metabolism in insects and established a striking parallel in the metabolism of the amino-acid between mammals and insects. Pyridoxine had earlier been shown by the same author[5] to be an essential vitamin for the growth of the larva. The excretory pigment, however, was not characterized; but it was shown that it was not identical with xanthurenic acid, from the negative test it gave with iron salts. Tryptophane has also been shown to be the precursor of the pigments, ommochromes, found in the eyes and tissues of certain insects, and the production of the pigments appears to be controlled by genes[6]. Kynurenine and hydroxykynurenine, which are normal intermediates in this conversion, and kynurenic acid, which is derived from kynurenine by oxidative deamination consequent on a gene mutation, have all been identified and isolated[-9]. The present communication outlines further studies of the metabolism of tryptophane in the rice moth larva. The effect of the incorporation of DL-kynurenine and of D-tryptophane in the diet instead of DL-tryptophane and the chemical identity of the excretory pigment have been investigated.

The experimental technique was the same as that described by Sarma[5]. It was found that DL-tryptophane and DL-kynurenine, ingested at a level of 1 per cent in the larval diet, gave rise to yellow-coloured fæces, whereas D-tryptophane, at a level of 0·5 per cent, did not yield the same result, the colour of the excreta being white.

The role of the vitamin, pyridoxine, in tryptophane metabolism is well known[1]. In the reaction sequence, tryptophane → kynurenine → 3-hydroxykynurenine → 3-hydroxyanthranilic acid → nicotinic acid, pyridoxine takes part in the conversion of 3-hydroxykynurenine to 3-hydroxyanthranilic acid, by acting as the prosthetic group of the enzyme, kynureninase, in the form of pyridoxal phosphate[2]. Thus a deficiency of the vitamin would lead to a block in the metabolic conversion of tryptophane at the stage of kynurenine or 3-hydroxykynurenine, both of which are coloured yellow and would be excreted as such or as conjugates. It is interesting, however, that unlike in the mammals the kynurenines are not further converted in the rice moth larva to xanthurenic acid. This was confirmed by the absence of the spot corresponding to this metabolite when the pigment was chromatographed on paper against an authentic sample of xanthurenic acid. The replacement of DL-tryptophane by DL-kynurenine for the same reason would be expected to yield essentially the same result, and, as already mentioned, this was actually found to be the case in feeding trials with the larvæ.

The metabolism of D-tryptophane in the larva was investigated with the view of comparing it with that in mammals. It is known that the rat, unlike the rabbit, can utilize the D-isomer of tryptophane as well as the L-isomer for growth and other metabolic purposes[1,10]. This is attributed to the action of the enzyme, D-amino-acid oxidase, in the tissues, which oxidatively deaminates the D-isomer to the keto-acid, which is then converted back to the amino-acid in the L-form. It has been found[11,12] that, in general, the highest concentrations of the enzyme are found in carnivorous, the lowest in herbivorous and intermediate in omnivorous organisms. On the basis of these results, therefore, the rice moth larva cannot be expected to be rich in the enzyme, and this is borne out also by the failure of D-tryptophane to be utilized, as reflected in the absence of pigment in the fæces. However, this was confirmed by the actual determination of D-amino-acid oxidase activity in larval tissues, using D-tryptophane as the substrate. The D-isomer was incubated with a pyrophosphate buffer[13] extract (pH 8·3) of normal larval tissue and the ammonia formed was determined by the Nessler reaction. It was observed that D-tryptophane did not yield ammonia over and above that liberated for the blank.

It is thus clear that D-tryptophane is not deaminated by the larval enzyme system, though unequivocal proof as to the complete absence of the enzyme, D-amino-acid oxidase, must await more detailed investigation with the isomers of proline and methionine, which are acted upon more readily than D-tryptophane[12]. Investigations in this direction are in progress.

The larval excretory pigment has been chromatographed on paper using two separate solvent mixtures, namely, butanol–acetic acid–water employed by Dalgliesh[3] and butanol–methanol–benzene–water adopted by Mason and Berg[14]. The former solvent system was found to give better resolution, but the results from the two series were interpreted cumulatively. One of the constituents of the pigment appears to be kynurenine or a derivative thereof, and another hydroxykynurenine, from their R_F values by chromatography against authentic samples of these substances, their fluorescence in ultra-violet light, colour reactions with Ehrlich's reagent and other specific chemical tests.

The excretory pigment has also been successfully chromatographed from an aqueous alcoholic solution on a column of acid-washed alumina, development being done with $M/10$ sodium phosphate. The interesting observation was made that both DL-tryptophane and DL-kynurenine in the larval diet yielded almost identical chromatographic patterns and fractions with similar ultra-violet characteristics.

These and related results will be published in detail elsewhere.

We would like to express our thanks to Dr. C. E. Dalgliesh and Dr. W. E. Knox for their generous gifts of DL-kynurenine and xanthurenic acid respectively.

Are *Torulæ* Haploid?

At irregular intervals, yeast geneticists have reported[1] the origin of asporogenous yeast types by the direct germination of spores. Naturally, they were entitled to believe that asporogenous yeasts generally referred to as *Torulæ* may have had a similar origin. Their suggestion that all asporogenous strains are 'haploid' could, however, be considered valid only if polyploidy did not occur in yeasts.

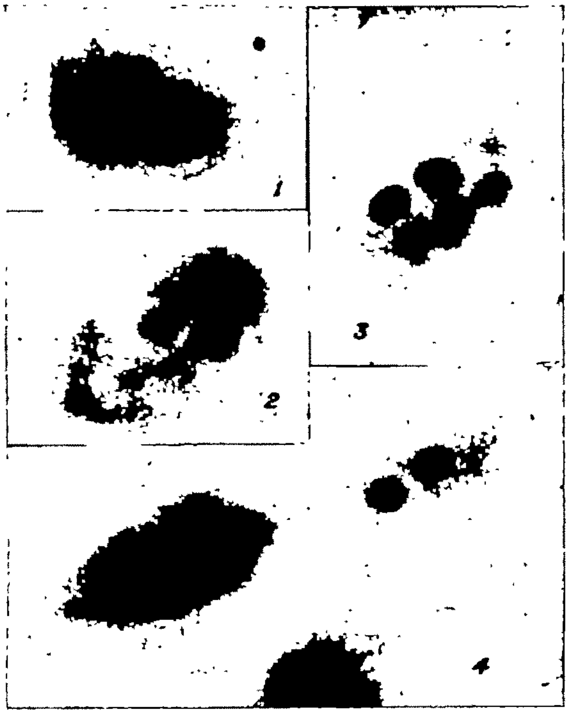
The demonstration of induction of tetraploidy in a brewery yeast in this laboratory[2] stimulated our interest in the problem. It was argued that if tetraploidy was common in yeasts, the spores of diploids should be different from those of polyploids in their chromosomal constitution[3], and hence the direct germination of a spore to give rise to an asporogenous type cannot be taken as critical evidence for haploidy.

The occurrence of spontaneous and induced tetraploidy in yeasts[4] rendered unreliable the highly variable morphological criteria employed by yeast geneticists for distinguishing 'haploids' from 'diploids' for the obvious reason that these do not enable a differentiation of the diploids from the polyploids[5].

Subramaniam[1] indicated the possibility that *Torulæ*, instead of being haploids, may really be sterile diploid hybrids. Support for this contention was offered by Windisch's[6] interesting observations on sporulation by a strain of *Torulopsis pulcherrima*. In higher plants it is known that a sterile diploid hybrid could give rise to a fertile allotetraploid. The present series of investigations on a strain of *Candida utilis* (Henneberg) Lodder and Kreger-Van Rij[7] (N.C.T.C. India, 3,010) was planned to elucidate its cytological behaviour.

A loop of yeast from a 12-hr. old culture was inoculated into a 50-ml. conical flask containing a thin layer of wort. After growth for 16 hr., the contents of the flask were shaken, most of them discarded and the remainder, mixed with 150 ml. of filtered wort, were transferred to a sterile aerator. Compressed air was bubbled through the medium using a sintered glass candle. After 6 hr., samples were removed at intervals of five minutes, centrifuged and smears prepared as usual[8]. The smears were fixed with osmic acid vapour and stained by the Feulgen technique[9].

At early prophase the nucleus contains a single chromatin mass (Fig. 1). The two chromosomes originating from the above are illustrated in Fig. 2 (cf. Thomas[10]). These reproduce, and at early anaphase four daughter chromosomes could be observed separating as two pairs (Fig. 3). One pair migrates to the bud. In Fig. 4, the two chromosomes in the mother cell are synapsing while those in the bud still remain discrete.



Longest diameter of cell: (1) 3·6 µ, (2) 3·6 µ; (3) 3·6 µ; (4) 7·2 µ (mother cell with bud)

Attention is invited to the remarkable similarity between the mitotic behaviour of *Candida utilis* and that reported earlier for the sporogenous two-chromosome brewery yeast[11], *BY* 1. The minimum number of chromosomes necessary for normal meiosis is only two, and hence the inability of our strain of *Candida* to sporulate must be due to other factors. It is quite likely that it may be a diploid hybrid in which the chromosomes are unable to pair as a necessary precedent to normal meiosis. If that is so, a doubling of the chromosome number in this strain should make it a sporogenous one (cf. ref. 6). The possession of a basic chromosome complement essential for sporulation indicates that the strain of *Candida utilis* studied cannot be considered a haploid.

Diploid yeasts have been reported to be asporogenous[1,12]. The mere fact that a strain has originated by the direct germination of a spore, or that it is incapable of sporulation, does not entitle one to conclude that it is a haploid. Are we then justified in believing that the various strains of *Torulæ* could have originated by the direct germination of haploid spores with concurrent loss of ability to become diploids?

Prochromosomes and Supernumerary Chromosomes in *Rhinanthus minor* Ehrh.

THE resting nucleus of *Rhinanthus minor* Ehrh. is characterized by the presence of a variable number of irregular bodies which stain with Feulgen's stain. These bodies were described as occurring in the genus *Alectorolopus* (= *Rhinanthus*) by Witsch[1], who regarded them as fused chromocentres. There are usually four to eight of the bodies in the resting nucleus although the number varies between one and fourteen. They are visible under certain conditions in the living cell and cannot therefore be regarded as artefacts due to fixation. There is usually one nucleolus (rarely two) in the resting nucleus. Each nucleolus is closely appressed at one or more points to one or more of the stainable bodies. The connexion is such that, where a single nucleolus is present, it is sometimes pulled into a spindle shape,

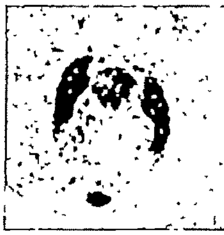

Fig. 1. Resting nucleus of *R. minor* showing three prochromosomes lying against the nuclear membrane. The single nucleolus is attached to two of the prochromosomes by apparently double attachments. (× 1,200)

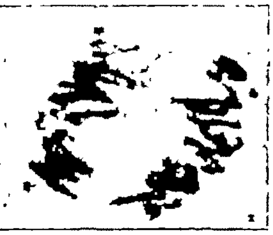

Fig. 2. Anaphase of *R. minor* in which four small *V*-shaped supernumerary chromatids may be seen in one of the anaphase plates. (× 2,400)

more rarely a triangle or rectangle, the two, three or four points of contact with the stained bodies representing the respective apices of these figures.

At mitotic prophase the nucleoli disappear and each of the stained bodies gives rise directly to one or more chromosomes, which as they become distinct can be seen to possess the relic coils of the previous metaphase. The prophase chromosome has a long unstained distal region, the centromere being in most cases sub-terminal. It would seem from the foregoing evidence that the major part of the prophase chromosome (the stained region) arises directly from one of the stainable bodies in the resting nucleus, each of which may contain one or more chromosomes. At metaphase satellites have been observed attached to two of the complement. Distortion of the nucleolus is consistent with the view that the satellite may be contained in one body and the remainder of the chromosome in another; these would be connected by a thin unstained nucleolar organizing region passing through the nucleolus. Alternatively, it is possible that there are four nucleolar organizing regions in the complement.

In view of the evidence that the chromatic bodies contain part of, if not all, the chromosome, the term 'prochromosome' might be more suitable than the term 'chromocentre', which is usually applied to bodies which occur in constant number in the resting nucleus and which represent heterochromatic regions of chromosomes.

In late prophase and metaphase a number of supernumerary chromosomes become stainable. At metaphase these are seen to be double, and at anaphase pass to the poles perfectly regularly. At least four of these possess a median centromere (visible at metaphase) which gives rise to a *V* configuration at anaphase (Fig. 2). These supernumerary chromosomes occur in root and shoot and have not yet been observed to be lost at anaphase. They are much smaller than the 'normal' complement and stain feebly, and can therefore be counted only with some difficulty. The maximum number of these small chromosomes yet found is eight.

The diploid number for *Rhinanthus minor* Ehrh. is 14. In addition to this constant count there is a number, possibly variable, of supernumerary chromosomes.

Origin of Reverse Thermo-remanent Magnetism of Igneous Rocks

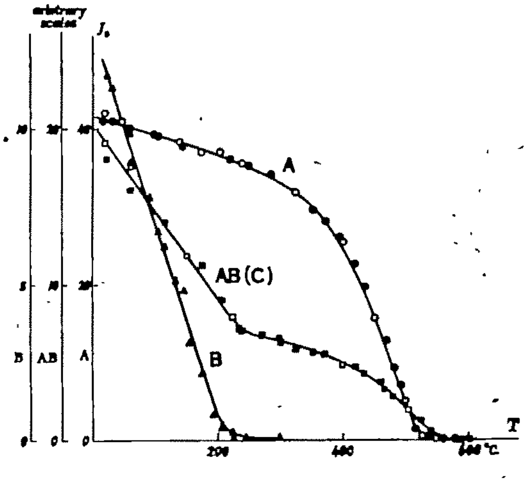
IN a previous article[1], one of us (T. N.) reported the phenomenon of self-reversal of the thermo-remanent magnetization of the ejecta of Mt. Haruna and of the ferromagnetic minerals separated from the rocks. It was also proved experimentally that the characteristics of the reverse thermo-remanent magnetization of the ferromagnetic minerals are the same as those of reverse thermo-remanent magnetism of their mother rocks.

For the physical mechanism of the production of reverse thermo-remanent magnetism, Néel[2] proposed a possible process in which the ferromagnetic minerals are composed of two different constituents of widely different Curie point; the magnetization of the constituent of lower Curie point is affected by the demagnetizing field arising from the magnetization of the constituent of higher Curie point. The characteristics of the reverse thermo-remanent magnetism of the Haruna rocks obtained so far seem to agree fairly well with this assumption[3].

In order to examine this assumption more directly, the ferromagnetic minerals of the Haruna rocks have been investigated. Ferromagnetic material, of mean diameter 0·3 mm., was separated magnetically at high temperatures in nitrogen gas. The result showed that the grains can be divided into three groups: namely, *A*-grains, which are strongly magnetic at temperatures higher than 300° C.; *B*-grains, which are non-magnetic at temperatures higher than 300° C. but are magnetic below 200° C.; and *C*-grains, which have weak magnetic properties at temperatures higher than 300° C.

The change of saturation magnetization (J_s) with temperature (T) of these three kinds of grains was measured. The accompanying graph illustrates the change of J_s with temperature of each class of grain, *A*, *B* and *C*. The Curie points of the *A*- and *B*-grains are almost 530° C. and 230° C., respectively, and the J_s–T curve for *C*-grains is similar to the resultant of the superposition of that of *A* and *B*. In other words, each single *C*-grain consists of two constituents, *A* and *B*, so that the *C*-grain will be denoted by *AB*.

Experiment shows that the thermo-remanent magnetization of both *A*- and *B*-grains has the normal direction, being parallel to the applied magnetic field, at atmospheric temperature, while that



Curve *A*, ●, heating process; ○, cooling process. *AB*(*C*), ■, heating process, □, cooling process. *B*, ▲, heating process; △, cooling process of the AB-grains in the same condition is the reverse. This self-reversal of thermo-remanent magnetization takes place even in a single AB-grain. It may be concluded, therefore, that the magnetic interaction between the A- and B-constituents within each AB-grain is responsible for the reverse thermo-remanent magnetism of the whole group of ferromagnetic minerals as well as for that of their mother rocks. It may well be that the thermo-remanent magnetization of the B-constituent within an AB-grain is developed under the effect of a demagnetizing field caused by the neighbouring A-constituent within the grain, so that the magnetization of the B-constituent is opposite to the applied magnetic field. The reverse remanent magnetization of the B-constituent becomes larger than the normal magnetization of the A-constituent at atmospheric temperature. The plausibility of the latter argument may be verified by comparing the steep temperature gradient of J_t in the case of the B-constituent with the small gradient of the A-constituent, shown in the graph.

So far as the reverse thermo-remanent magnetism of the Haruna rocks is concerned, the general principle of Néel's theory appears applicable; but it seems to need a slight modification since the magnetic interaction between the two constituents within each grain only is effective, the interaction between the separate grains of different kinds being not primarily significant. It has been proved, in addition, that the A-constituent is nearly stochiometric magnetite, while the B-constituent is rich in titanium oxide (TiO_2). The detailed chemical and crystallographic examination of each mineral constituent is now proceeding.

With reference to the basaltic rock mass at Genbudo, Japan (Tertiary lava), which according to Matuyama[4] has remanent magnetization almost opposite to the present geomagnetic field, this rock shows no positive evidence of reverse thermo-remanent magnetism such as is found in the Haruna rock.

Note added, April 9. A study of the article entitled "Magnetic Properties of Rocks" in *Nature* of March 21 suggests the following comments.

We have examined the magnetic properties of a Whin Sill sample, which was sent us by courtesy of H. Manley. The result shows that the direction of its thermo-remanent magnetism is perfectly parallel to the magnetic field, and its other magnetic properties are completely normal. Among a number of other Japanese samples examined so far, only the dacitic pitchstone of Ashio showed reverse thermo-remanent magnetism similar to that of the Haruna dacite. Hence we do not claim that all igneous rocks having adverse magnetization *in situ* have the character of the adverse thermo-remanent magnetism due to Néel's two-component mechanism.

We are much interested in the report that many experiments in England and in France on the magnetic properties of naturally adversely magnetized rocks gave a negative result for Néel's mechanism. At the same time, we cannot ignore the interesting fact of the adversely magnetized gneisses found by Buddington. The magnetic properties of his samples must also be studied in detail, and we are now going to do this. Thus, although we agree with the argument that a large number of igneous rocks having natural adverse magnetization *in situ* have the normal characteristics of thermo-remanent magnetism in its ordinary meaning, we still hesitate to conclude finally that the earth's magnetic field was reversed during certain geological times, because, from our recent studies, the magnetic properties of igneous rocks seem to be much more complex than their other properties. For example, the ferromagnetic minerals even in a small piece of rock show a wide range of Curie point, and the presence of magnetic interaction between closely neighbouring ferromagnetic constituents is rather usual, though it is in many cases not strong enough to result in reverse thermo-remanent magnetism.

Until, therefore, the physics of the magnetic properties of rock-forming ferromagnetic minerals are well established, the possibility should not be rejected that there exists an unknown mechanism for producing adverse remanent magnetization. The reversal of the magnetic field of the earth during its history must not be assumed without further evidence.

We thank Prof. Néel for discussion.

Radiocarbon Dating: Large-scale Preparation of Acetylene from Organic Material

THE introduction of the radiocarbon method of dating materials of organic origin by Libby, Anderson and Arnold in 1949[1] provided the archæologist with an important new tool, and the number of inquiries received by the British Museum laboratory immediately after the announcement indicated the need for carbon-14 dating facilities in Great Britain. As the British Museum laboratory seemed to be the appropriate body to administer such a service, an approach was made in July of that year (1949) to the Atomic Energy Research Establishment, Harwell, for help and advice in setting up such a service.

After investigating the whole problem, the Atomic Energy Research Establishment advised an alternative approach to that of Libby, Anderson and Arnold, namely, conversion of the carbon in the sample to a gas (preferably a diatomic one such as acetylene or ethylene) and subsequent counting of the carbon-14 activity in a proportional counter. While this course of action might result in a long delay before a dating service was available, owing to the amount of research and development necessary, it could possibly lead to two important improvements from the archæological point of view, namely, reduction of sample requirements and increased accuracy of the calculated dates.

Work on the problems of quantity production of acetylene was begun at Harwell in October 1950, and transferred to the British Museum laboratory a few months later, where a plant was built so that the chemical problems could be studied in parallel with those of counter design at Harwell.

Later, in 1951, as a result of an independent approach to the Atomic Energy Research Establishment by the Royal Institution, more resources became available for counter design, and since May 1952 there has been close collaboration between the Royal Institution and British Museum laboratories, it being agreed that the problems of acetylene production and the associated analytical control problem of acetylene and lithium purity should continue to be examined at the British Museum.

The method of acetylene production is based on that of Arrol and Glascock[2] for the conversion of carbon dioxide to acetylene on a microscale, but using lithium instead of barium. The sample is burned in a stream of oxygen at atmospheric pressure in a silica furnace of special design—there being difficulties with the traditional copper oxide packing when burning material which yields large quantities of volatile products. The resulting carbon dioxide is freed from water vapour and other condensible impurities by passing through traps cooled to − 78° C. and is condensed in further traps at liquid-oxygen temperature. When the combustion is finished, non-condensable gases are pumped away and the carbon dioxide is expanded into storage bulbs until required. The carbon dioxide is then allowed to react with an excess of metallic lithium at high temperature (700° C.) in a stainless-steel furnace of the type described by Arrol and Glascock[2], to give lithium carbide. Acetylene is then obtained from the carbide by the addition of carbon dioxide-free, distilled water.

Good yields of carbide are favoured by using a large excess of lithium and allowing the reaction (which is exothermic) to proceed at as high a temperature as possible. Good yields of acetylene are only obtained in practice if the final concentration of lithium hydroxide in the furnace after the addition of water is not much in excess of 5 per cent, since the rate of evolution of acetylene from lithium carbide falls off markedly as the concentration of lithium hydroxide rises. In practice, it has been possible to obtain approximately 65 per cent efficiency for the conversion $CO_2 \rightarrow C_2H_2$ by employing a 50 per cent excess of lithium and a furnace of such dimensions that the final concentration of lithium hydroxide was not greater than 10 per cent. This should be improved upon when a large furnace becomes available.

After liberation from the carbide, the acetylene is freed from condensable impurities by passage through a trap at − 78° C. and is condensed at liquid oxygen temperature, while hydrogen liberated at the same time by reaction of the excess lithium with the water is pumped away. The acetylene is finally purified by repeated passage over solid adsorbents.

It is hoped in the New Year to complete the installation of carbon-14 dating apparatus incorporating these processes and the counting techniques developed by the Atomic Energy Research Establishment, Harwell, and the Royal Institution, thus providing at the British Museum laboratory a complete dating system which will be used in the service of archæology.

I wish to thank the Director of the Atomic Energy Research Establishment, Harwell, for the generous provision of facilities, and Dr. W. J. Arrol, Isotope Division of the Establishment, for his help and encouragement in the early stages of the work.

Use of an Acetylene-filled Counter for Natural Radiocarbon

THE use of natural carbon-14 activity for purposes of archæological dating was suggested by Libby, who used a screen-wall counter[1]. The majority of workers in this field have employed the same type of counter in which the carbon is introduced as a solid. However, the counting of carbon-14 in its elementary form appears to be inherently a method of low efficiency, and the alternative use of a counter in which the filling gas is also the sample seems to offer greater scope for improvement. This has been the subject of several recent publications. De Vries and Barendsen[2] have used carbon dioxide as the sample gas, and Faltings[3] has considered the use of methane as an alternative to carbon dioxide. A further improvement may be sought by the use of a gas containing more than one carbon atom per molecule, and to this end an apparatus has been constructed in this laboratory for the counting of natural radiocarbon in the form of acetylene.

The operating conditions for a counter which will produce the best statistical accuracy for a sample rate of counting S, where the background rate B is random, is given by the largest obtainable value for S^2/B. In general, this ratio will increase with increasing size of counter and will increase more rapidly with size for a gas-sample counter at constant pressure than for a solid-sample counter. This follows from the fact that the ratio S/B also increases for the former counter but remains approximately constant for the latter. This is shown in an analysis by Anderson and Levi[4]. On these grounds the gas counter should be as large as possible; but in practice limits are set by the difficulties of shielding and by the desirability of not too high an operating voltage.

In the work outlined here a mild steel counter of about three litres volume is employed and thus 3 gm. of carbon may be introduced by filling to one atmosphere pressure with acetylene. The counter is surrounded by eleven Geiger counters used in anti-coincidence and the whole array is enclosed in a 4-in. thick lead shield. The sample counter is operated in the proportional region and a further reduction in background is thus obtained by discriminating against small pulses; in this way some of the smallest β-particle pulses from the decay of carbon-14 are also lost and the optimum discriminator setting is determined by plotting bias curves for background and sample-plus-background counts. The background counting-rate is obtained by filling the counter with acetylene produced from anthracite, which contains no carbon-14. Under standard operating conditions, this value for the background is 30 c.p.m. A figure for the efficiency of the counter for detection of carbon-14 may be obtained by filling it with acetylene made from modern biological material such as contemporary wood. For such material Libby has found the specific activity to be 15·3 disintegrations per min. per gm. Maintaining the same operating conditions as for the background determinations and filling the counter with acetylene made from contemporary wood, the count-rate is 64·5 c.p.m. This corresponds to an efficiency for carbon-14 of 75 per cent at the optimum discriminator setting: minimum discriminator setting gave a counting efficiency of 90 per cent but poorer sample statistics. The figure quoted by other workers using screen-wall counters is about 5 per cent.

The acetylene is prepared in this laboratory from organic material as described by Dr. H. Barker (p. 632).

Further improvements over the figures so far obtained may be sought by improvements in shielding and by the use of acetylene at pressures in excess of atmospheric. A full description of the apparatus and method will appear elsewhere.

My thanks are due to Prof. F. E. Zeuner, of the Institute of Archæology, London, for his part in the initiation of this work and for his continued interest. Preliminary studies of gas production and counter design were made at the Atomic Energy Research Establishment, Harwell, and I wish to thank the Director for the generous provision of facilities, and members of the Isotope and Electronics Divisions for their assistance.

Daily Variation of Amount of Ozone in the Atmosphere

THE improved form of Dobson's spectrophotometer using an *RCA* 1P28 photo-multiplier tube enables measurements of atmospheric ozone to be made with the light from the moon. Dobson's own measurements[1] made at Oxford during November–December, 1948, showed variations of ozone on some nights, and he concluded that they could be attributed to changes in meteorological conditions. As the day-to-day variations of amount of ozone in middle latitudes are large, it would be difficult to find without prolonged observation whether there is any systematic difference between the ozone amounts during day- and night-hours. In low latitudes, however, both the total amount as well as the day-to-day variations are small during a large part of the year, and if a regular daily variation exists as might be expected from the photochemical theory of atmospheric ozone, it could be determined from a short series of observations. Accordingly, observations were made at Mount Abu and Ahmedabad in the period November 1952–April 1953, and these show clearly that there is a substantial increase of ozone during night-hours, as compared to day-hours.

Fig. 1 shows the values of log(I/I') against μ, the thickness of ozone traversed by the incident light at different zenith-distances of the sun or moon, where I is the intensity of a small ozone-absorbed spectral region near λ 3112 and I' the corresponding intensity near λ 3323 in a less-absorbed region of the spectrum, on four days and succeeding moonlit nights. It will be seen that on each day the mean straight line connecting the night observations has a steeper slope than the line connecting the day observations, indicating a larger quantity of ozone in night.

Table 1. SUMMARY OF OZONE VALUES DURING DAY AND DURING NIGHT. x is the amount of ozone in cm. at S.T.P. No correction has been made for atmospheric haze

Date	Day value of x in cm.	Night value of x in cm.	Difference
29–11–52	0·138	0·163	0·025
30–11–52	0·137	0·162	0·025
1–12–52	0·136	0·160	0·024
2–12–52	0·135	0·157	0·022
22–12–52	0·141	0·171	0·030
23–12–52	0·139	0·172	0·033
24–12–52	0·147	0·174	0·027
26–12–52	0·146	0·188	0·042
27–12–52	0·147	0·191	0·044
28–12–52	0·151	0·170	0·019
29–12–52	0·148	0·184	0·036
30–12–52	0·147	0·177	0·030
1– 1–53	0·141	0·173	0·032
2– 1–53	0·140	0·176	0·036
23– 3–53	0·164	0·207	0·033
27– 3–53	0·166	0·196	0·030
3– 4–53	0·179	0·205	0·026

Table 1 gives the mean day- and night-values of ozone (both uncorrected for haze) on seventeen days and nights. In every instance, the night values are larger than the day values. The average excess during night is 0·030 cm. and the extreme differences are 0·019 cm. and 0·044 cm.

Table 2. OBSERVATIONS WITH λλ 3112 AND 3175

Date	Day-time x	Night-time x With λ 3112	Night-time x With λ 3175
30–11–52	0·137	0·168	0·174
1–12–52	0·137	0·165	0·168
1–12–52	0·136	0·161	0·149
2–12–52	0·135	0·168	0·162
27– 3–53	0·166	0·196	0·197
3– 4–53	0·179	0·205	0·203

Observations made at Ahmedabad on the same night with λ 3112/3323 and λ 3175/3399 show agreeing results. Table 2 gives the comparative values of ozone obtained with the two pairs of wave-lengths.

Fig. 2 shows the values of ozone calculated from the individual observations of sunlight and moon-

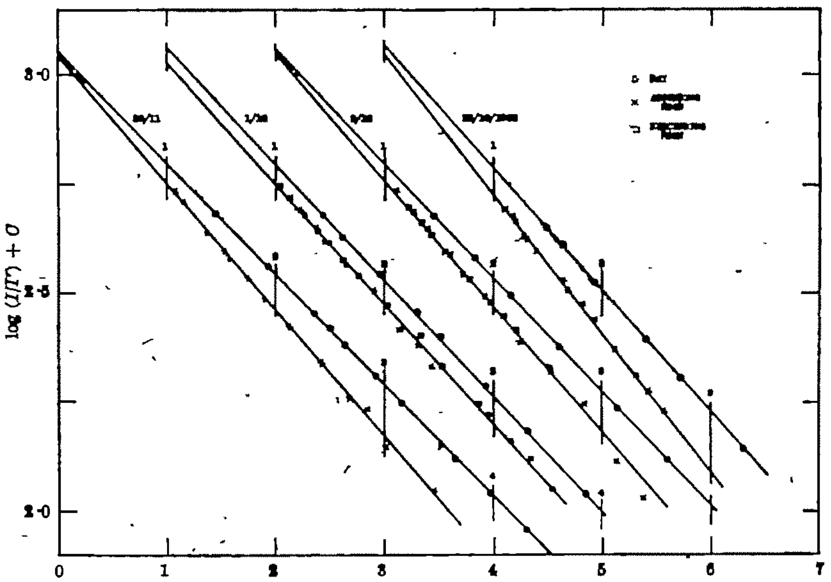

Fig. 1. Values of log (I_{3112}/I_{3323}) + C plotted against atmospheric ozone path with sunlight and moonlight

light on a number of days. The increase of ozone from the day value to the night value takes place within an hour after sunset. The change from night to day value after sunrise is also rapid. These indicate that the seat of the observed changes is high up in the atmosphere, where the recombination of oxygen atoms and molecules to form ozone after sunset and the photolysis of ozone at sunrise are very rapid. It may be expected that these daily variations of ozone extend to higher latitudes.

Estimates have been made by H. U. Dütsch[2], R. A. Craig[3], D. R. Bates and M. Nicolet[4] and Johnson, Purcell, Tousey and Watanabe[5], of the number of oxygen atoms at different levels in the atmosphere from 30 km. to 90 km. during day-time. From the values calculated by F. S. Johnson and collaborators using the rocket-data of intensity distribution in solar radiation in the ultra-violet, the equilibrium amount of daytime atomic oxygen in the atmosphere can be shown to be approximately 0·020 cm. between 90 and 70 km., and 0·010 cm. between 70 km. and 40 km., with the amount decreasing rapidly at lower heights.

This suggests that the night-time increase of ozone is due to the recombination of 'odd oxygen atoms' with oxygen molecules above the region of maximum ozone concentration and below the main region of Runge–Schumann oxygen absorption.

It may be noted in passing that extraordinarily low values of ozone were recorded at Mount Abu on many days in November and December 1952.

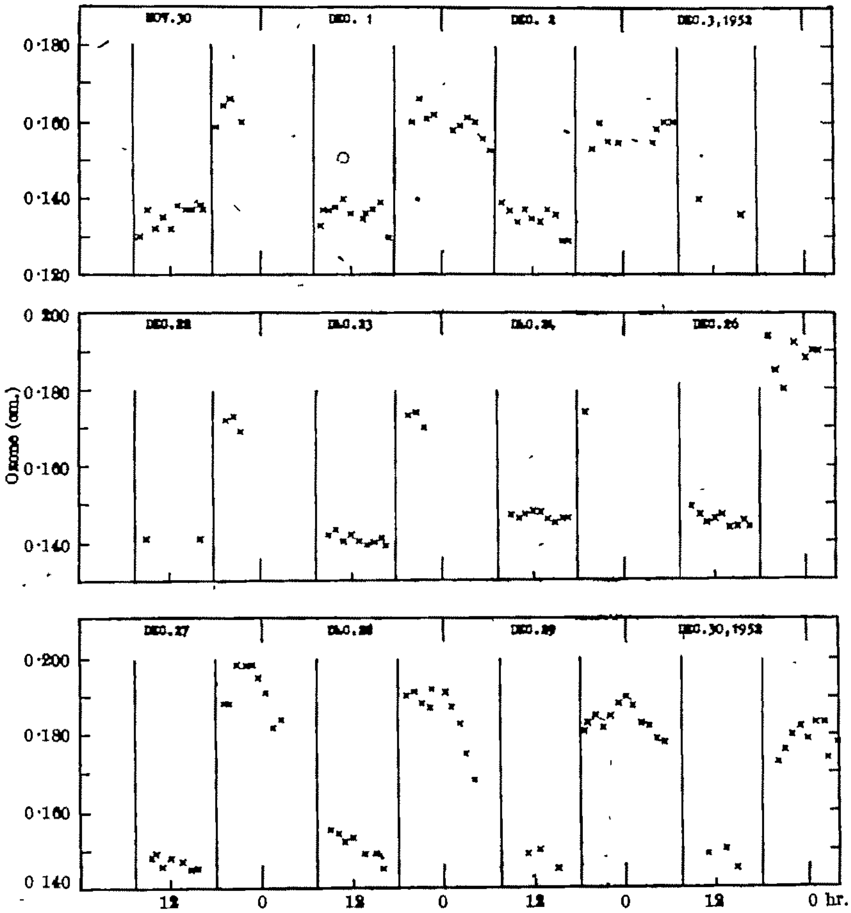

Fig. 2. Values of atmospheric ozone measured at Mt. Abu with sunlight and moonlight

Our thanks are due to Mr. R. N. Kulkarni for taking some of the observations, and to the Indian Council of Scientific and Industrial Research for financial assistance to carry out research work on atmospheric ozone.

A fuller discussion will appear elsewhere.

Eddies in Turbulent Jet Diffusion Flames

The turbulent jet diffusion flame may be defined as a flame in which a high-velocity jet of fuel entrains the combustion air by its own momentum. In such flames the rate of combustion is primarily governed by the rate of mixing once the fuel stream has been heated by re-radiation above an ignition temperature. The use of cold models and accepted formulæ for free jets to evaluate the entrainment-rate is accordingly a valuable method of predicting combustion-rates. Such models give time-average mixing ratios at each point in space which may be compared with the analysis of time-average gas samples drawn from the flame, and in each case repeatable regular contours for equal mixing ratios are obtained.

Visual inspection of a luminous flame shows, however, rapid large-scale eddies in the flame structure which correspond to the fluctuating random component of turbulent flow. This is shown in Fig. 1, which was taken on a 3,000 frames/sec. ciné film with approximately 1/15,000 sec. exposure. To relate this instantaneous pattern with the smooth time-average pattern given by slow sampling techniques, a 20-sec. exposure has been taken of the same part of the flame with an appropriate neutral density filter. This is shown in Fig. 2, on which the jet angle is 12½°. Empirical formulæ relating mixing length to jet momentum can be adequately based on the time-average conditions, but an understanding of the mechanism of mixing and combustion requires a knowledge of the eddy structure which can be related to hot-wire measurements of fluctuating velocity.

Antibody Chromatography on an Immunologically Specific Adsorbent

While usual chromatographic methods have not, in general, proved as useful in the separation of closely related proteins as of low molecular weight substances, chromatography on adsorbents which bind only to the specific reactive sites of biologically active proteins may help to fill that need. I wish to report here the feasibility of elution chromatography of an antibody on its specific adsorbent. The antibody proteins are not only separated from the other constituents of serum, but are, in addition, resolved into components which remain active and distinguishable on repeated chromatography.

An adsorbent specific for antibodies homologous [illegible] simple hapten, *p*-azobenzenearsonate, was [illegible] from powdered cellulose (Solka-Floc BW200, [illegible] Brown Company, Berlin, N.H.) by a [illegible] hat described for an adsorbent [illegible] inase[1]; diazotized *p*-(*p*-amino-[illegible] rsonic acid was coupled to [illegible] had been partially etherified with [illegible]. This approach has been adapted to permit the permanent attachment of a protein, which retains its reactivity to the homologous antibody, to the surface of suitably modified cellulose[2]. The arsonate cellulose binds maximally about 2 mgm. of antibody protein per ml. of packed moist adsorbent. An analogous cellulose preparation in which *p*-azo-[illegible]enzenesulphonate is substituted for the homologous [illegible]apten was found not to adsorb detectable amounts [illegible] antibody.

Chromatography was carried out by gradient [illegible]tion, for the reasons given by Alm *et al.*[3], with a [illegible]cific hapten solution as the eluent. The chromato[illegible]m shown in Fig. 1,I was obtained as follows. [illegible]ter a small amount of serum (0·16 ml. serum diluted [illegible]0·7 ml. in saline buffered to *p*H 8·0) was introduced into a column of adsorbent 13 cm. × 0·6 cm., saline was percolated through until the effluent was free of protein, as indicated by the absence of visible turbidity on the addition of trichloroacetic acid. The amount of antibody introduced corresponds to roughly 4 per cent of the maximum capacity of the column. The eluting hapten, sodium arsanilate, was then allowed to percolate through the column in increasing concentration at about 0·1 ml./min., and the effluent was collected in fractions of 0·5 ml. The concentration of arsanilate in the effluent is shown in Fig. 1,IV. Trichloroacetic acid was added (to a concentration of 10 per cent) to 0·1-ml. aliquots of the fractions; the protein precipitates were washed and measured with the Folin phenol reagent according to the procedure of Lowry *et al.*[4]. When a heterologous hapten, sodium sulphanilate, was used instead of sodium arsanilate, no protein was eluted at any concentration. The remaining portions of fractions 13–16 and fractions 17–24, to the left and right of the dotted line in Fig. 1,I, were combined into two pools and dialysed to remove arsanilate. The results of rechromatographing each pool on the same column as originally used are shown in Fig. 1,II and III. It is evident that each pool retains its position in the chromatogram, and, therefore, that the antibodies of each pool differ in their specific properties. The analytical values in these figures represent, however, the entire protein content rather than aliquots of each fraction, and indicate, therefore, a considerable overall loss of material. The arsanilate concentrations in corresponding fractions of chromatograms II and III, as determined by ultra-violet absorption of the supernatants after protein precipitation, were found to be in good agreement.

The heterogeneity of antibodies has previously been postulated and discussed in studies of hapten inhibition[5]. While the present experiments show that at least two kinds of antibodies homologous to a single hapten can be recognized and isolated, the actual heterogeneity may be much greater, since the pooling of fractions shown in Fig. 1,I into two groups was, of course, arbitrary. The proteins of

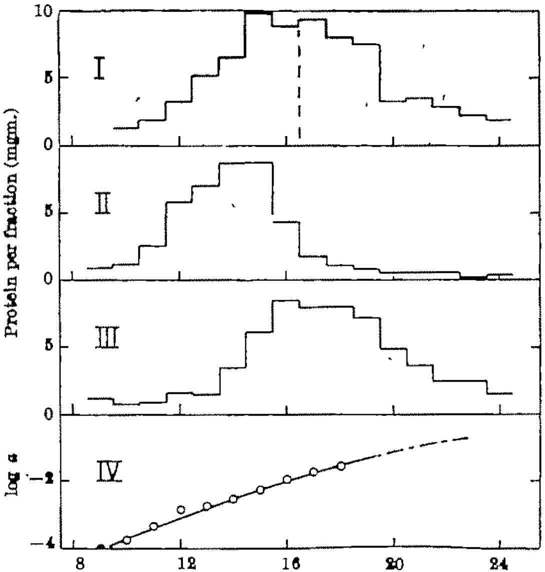

Fig. 1. Gradient elution chromatograms: I, whole serum, II, pooled eluate fractions 13–16 from I; III, pooled eluate fractions 17–24 from I. The arsanilate concentration, *a* (measured in *M*), appearing in each fraction is shown in IV

both pools were isolated in other similar experiments; both formed precipitates with polyhaptenic antigens.

This work was supported by the American Cancer Society and the Jane Coffin Childs Memorial Fund. A supply of rabbit antiserum against bovine globulin-azobenzenearsonate was kindly provided by Prof. D. H. Campbell of the California Institute of Technology.

I am grateful to Mrs. Shulamith Bar-Shany for technical assistance.

Nosean as a Tracer Mineral

Eight miles south of Land's End stands the well-known Wolf Rock with its important lighthouse. The rock itself is a phonolite, the only one of its kind on the whole of the coast of the British Isles. Its petrography was accurately described by J. J. Harris Teal in 1888 ("British Petrography", Dulau and Co., London).

For our purpose the all-important mineral is nosean, a somewhat soluble sodium aluminium silicate with sodium sulphate; but fortunately it is found in two stages. It occurs as phenocrysts which are useless for the present purpose because of their solubility in sea-water, and it also occurs as inclusions in the felspar sanidine, as minute grains which are thus hermetically sealed within this colourless mineral which is practically as resistant to sea-water as quartz itself. Actually, one can boil small flakes of the sanidine in fairly strong hydrochloric acid without the nosean being destroyed.

Thus the nosean would appear to constitute an ideal tracer mineral for investigating the direction of deep, or bottom, sea-water drift around the British Isles.

Owing to the kindness of Major H. W. Hall, who readily placed his motor yacht *Manihine* at my disposal, we were able to carry out the first test on July 22.

Only one sample has been worked out so far, and that was one taken five miles east of the Wolf Rock at a depth of forty fathoms. It was thought that the work would entail a laborious microscopic examination of the bottom sand grains with the use of density fluids for floating off the sanidine flakes with the nosean. This, however, was found to be unnecessary in this case, for small pebbles of phonolite (about a third of an inch across) were readily separated out with a hand lens. These were crushed and the nosean enclosed in the sanidine recognized without difficulty.

Obviously, if pebbles of the phonolite are carried five miles away by the deep-water drift the minute flakes may be carried even hundreds of miles. Phonolite from the Wolf Rock has been broken up, and the nosean in conjunction with the sanidine is at once recognizable in flakes which are small enough to go through a 200-mesh sieve.

The refractive index of the sanidine is, of course, below that of the canada balsam, while that of the nosean is below that of the sanidine. This, coupled with the low density of the phonolite itself (2·54), makes the work comparatively simple and gives an indisputable diagnosis.

A. G. Lowndes

The Laboratory, Citadel Hill,
Plymouth. July 31.

Milk Yield of Hill Ewes

In the early stages the growth of the lamb is largely dependent on the milk yield of its dam. In hill sheep, where the environment constitutes the limiting factor to production, a study of the milking capacity of the ewe would seem to be of special interest, as it forms a large part of the lamb's environment at a most important period of growth.

Comparatively little work has been done on the lactation of non-dairy breeds of sheep, especially hill sheep. Some of the most extensive studies made on this problem are those by Bonsma in South Africa[1] and Wallace in Cambridge[2], although the sheep studied were not under natural conditions. Studies of the milk yields of sheep on pasture have been made by Barnicoat *et al.*[3] in New Zealand.

In the spring of 1953, an experiment was started at the University College of North Wales to study the milk yielding capacity of Welsh Mountain ewes, both under their normal hill conditions and after being drafted to the lowland.

Previous workers have usually obtained estimates of the ewe's milk yield by weighing the lamb before and after suckling at various intervals in a weekly 24-hr. period. Between sucklings the ewes and the lambs were separated. At Bangor, however, the separation of the ewe from the lamb was regarded as likely to be a disturbing factor, which might seriously affect milk yield, and an attempt was made to devise a method whereby the lamb was prevented from suckling, and at the same time allowing both ewes and lambs to go out on pasture together in between suckling periods. This was achieved by fitting the ewes with a harness which effectively prevented the lamb from reaching the ewe's udder, and at the same time was both comfortable for [illegible] ewe and easy to manipulate at suckling ti[illegible]

A pilot experiment using eight pe[illegible] Mountain sheep kept on the lowla[illegible] out early in the year to deve[illegible] nique. The experiment prope[illegible] April using thirty-two rando[illegible] with single ewe lambs on 'ff[illegible] about 1,000 ft. above sea-l[illegible] during the six weeks of the e[illegible] 6·04 oz. for the hill ewes com[illegible] the pedigree ewes during a short[illegible]m-inary analysis of this year's re[illegible]ligh[illegible] correlation coefficient ($r = +0·79$[illegible] th[illegible] milk yield of the ewe and the growth[illegible] lamb during the first month, demonstrating the [illegible]rtanc[illegible] of the dam's milk yield to the young lamb. [illegible]gnifica[illegible] correlations were also obtained between the m[illegible] yield of the ewe and the birth weight of the la[illegible] ($r = +0·51$) and the weight of the ewe at tupp[illegible] time ($r = +0·36$). Although there appeared to [illegible] a correlation between milk yield and some fle[illegible] characters these were not highly significant, [illegible] further work is needed to prove any relations[illegible]

These results, of course, being for one season only, must be confirmed and extended by further work before any conclusions are reached.

It is hoped to be able to increase the numbers used in the experiment in future, and to study the relationship of milk yield to such factors as fleece type, genetic influences, weight (both at lambing and tupping time), age, time of lambing and udder measurements. Some of the ewes included in this year's experiment will be drafted on to the lowland in order to study the effect on milk yield of the change from a poor to a good environment, as normally occurs when the hill ewe is drafted to the lowland.

Some observations have also been made on the quality of the milk, and it is hoped to extend these.

Finally, the effect of milk yield and other factors on the lamb will be studied.

Influence of Inorganic Sulphate on the Copper–Molybdenum Interrelationship in Sheep

In 1945 we published the first experimental observations[1] which showed that the storage of copper in the livers of sheep and cattle could be significantly reduced by an increase in the molybdenum intake, and we suggested that an abnormally high molybdenum intake may possibly explain, among other things, the seeming anomaly of copper deficiency in sheep-grazing pastures which show by ordinary chemical analysis a copper concentration within normal limits.

Since then a number of workers have studied the copper–molybdenum interrelationship in animal metabolism. Observations on this interrelationship are discussed in a number of the papers in the symposium [illegible] copper metabolism edited by McElroy and Glass[2], and more recently the literature has been reviewed by Marston[3].

Many of the observations and experimental results have been conflicting[1-4], and some workers[5] have not been able to confirm our original results.

In association with our studies on chronic copper poisoning in sheep[6,7], we have continued our observations on the effects of molybdenum on copper metabolism; and we believe that in the results of our more recent studies may lie the explanation of many of the anomalies and conflicting observations.

With sheep under experimental conditions, we have shown that, for a particular dietary regime, which included a total daily intake of 10 mgm. of copper, there is a quantitative relationship between the amount of molybdenum added to the diet and he reduction in the amount of copper stored in the ver. Under these conditions, on comparing groups sheep on successively greater daily intakes of olybdenum, all on a diet of equal parts by weight chaffed lucerne hay and chaffed oaten hay, it was und that progressively less copper was stored in *liver* as the molybdenum intake was increased m 0·4 mgm. to 10 mgm. per day. Further increases in the molybdenum intake, up to 100 mgm. per day, had no greater effect in limiting the amount of copper stored.

On this mixed diet, the level of molybdenum maintained in the circulating blood was increased as the molybdenum intake was increased. When these chaffed hays were fed separately to sheep, all on the same molybdenum intake, it was observed that the blood-molybdenum level was approximately ten times higher in the sheep on the oaten diet than in those on the lucerne diet. A comparison of groups of sheep[8], all on intakes of 10 mgm. of molybdenum and 15 mgm. of copper per day, but fed on the separate chaffed hays or on mixtures of several different proportions of these, showed that the greatest limitation of copper storage in the liver was obtained in sheep fed on the pure lucerne diet. Molybdenum appeared to exert no limiting effect at all in sheep on the pure oaten diet, and for the several diet mixtures the amount of copper stored in the liver and the level of molybdenum in the blood were directly proportional to the amount of chaffed oaten hay in the mixture.

We thus have the apparently anomalous position that as the blood-molybdenum level is raised by increasing the molybdenum intake of sheep, all on the same mixed diet, the amount of copper stored in the liver is progressively decreased; but as the blood-molybdenum level is raised by increasing the proportion of chaffed oaten hay in the diet of sheep, all on the same molybdenum intake, the amount of copper stored in the liver is progressively increased.

In a subsequent experiment of six months duration we have shown that with two groups of sheep, both having a total copper intake of 10 mgm. per day and a molybdenum intake of 0·5 mgm. per day, one group fed on chaffed lucerne hay and the other on chaffed oaten hay, the copper content of the livers of both groups increased. However, even at this low level of molybdenum intake, the group on the lucerne diet stored significantly less copper than the group on the oaten diet; in the former there was a gain of 55 mgm., increasing during the experiment from 39 mgm. to 94 mgm., and the latter 97 mgm., increasing from 40 mgm. to 137 mgm.

With two similar groups on a molybdenum intake of 10 mgm. per day, there was a loss of 13 mgm. (from 41 mgm. to 28 mgm.) of copper from the liver in the group on the lucerne diet, but the greater intake of molybdenum did not significantly affect the rate of copper storage in the group on the oaten diet; it increased by 70 mgm. (from 38 mgm. to 108 mgm.).

By fractionation of this chaffed lucerne hay we have shown[8] that the whole of its effect on the level of molybdenum in the blood is due to its content of inorganic sulphate which is present in amounts of the order of 0·3 per cent. The chaffed oaten hay contains less than one-tenth of this amount.

To determine whether the difference in inorganic sulphate content of the two diets was also responsible for the difference between them in enabling molybdenum to exert its limiting effect on copper storage, a further experiment has been carried out. A sufficient quantity of copper sulphate and ammonium molybdate was added to the diets of three groups of shee to *bring both the* copper and molybdenum intak up to 10 mgm. per day in each group. One grou was fed on chaffed oaten hay, one *on chaffed* lucer hay, and the third group on chaffed oaten hay wi 4·5 gm. potassium sulphate per kilogram added it. After a period of three months it was found that the first group had increased its liver-copper storage, but both the other two groups had lost copper from the liver and the amounts lost were substantially the same whether the diet was chaffed lucerne hay or chaffed oaten hay plus sulphate. In the first group liver-copper was increased by 19 mgm. (from 76 mgm. to 95 mgm.); it was decreased in the second group by 25 mgm. (from 76 mgm. to 51 mgm.), and in the third group by 26 mgm. (from 66 mgm. to 40 mgm.).

Inorganic sulphate is, therefore, required to enable molybdenum to exert a limiting effect on the storage of copper in the liver of sheep, and the difference in inorganic sulphate content of chaffed lucerne hay and chaffed oaten hay constitutes the major difference between them in their effect on the control of copper storage by molybdenum.

It seems, in the light of these observations and the wide limits between which both the inorganic sulphate and molybdenum content of natural pastures may vary, that the conditions under which copper deficiencies in grazing animals have been reported to occur should be re-examined. Furthermore, it would now appear that studies on molybdenum metabolism, especially on its retention and excretion, are valueless unless the inorganic sulphate intake of the animal is also taken into consideration.

Absence of the Sickle Cell Trait in Seventy-two Australian Aboriginals

The Veddoids of southern India have many physical features in common with the Australian aboriginals, and the Indian anthropologist, Dr. B. S. Guha, has actually suggested that the term 'Veddoid' or 'Veddian' should be replaced by the word 'Proto-Australoid'[1]. Whether the Veddoid element is equally strong in all Australian aboriginals is not certain. Birdsell[2] divides the Australian aboriginals into three groups; that in the Northern Territories is considered to have more Veddoid connexions than the other two, which are more intimately related to *Negritos* and Europoid Ainus respectively.

When one of us, jointly with Miss M. Cutbush[3], discovered the sickle cell trait to be present with a high incidence in the Veddoids of southern India, t was also found that their rhesus chromosome istribution showed features differing from those of ther Indian populations, and more like those found South-East Asia, Australasia, and especially in the Australian aboriginals. The rhesus chromosome *CDE* (R_z), which is rare, or absent, in most parts of the world, exists in Australian aboriginals at a frequency of several per cent rather than per mille[4,5], and was found at a frequency of 4·43 per cent in 156 unrelated south Indian Veddoids. This is the highest R_z frequency reported up to now outside Australia, and it was thus of interest to see whether the sickle cell trait could be traced in the Australian aboriginals.

From Birdsell's "Maps of Races"[2], it would seem that there is a Negrito influence in the north-west of Australia. This is relevant, because one of us has recently found that the Andamanese Negritos (52 pure Onges of Little Andaman and 16 Andamanese of mixed ancestry) show no sickle cell trait. However, everyone, including Birdsell, is agreed that the Carpentarian (Veddoid) element is strongly represented all over the northern half of Australia, including those parts from which we intended to obtain our blood samples. We arranged to have the blood of seventy-two Australian aboriginals from Queensland flown to London to be examined for the sickle cell trait. Fifty-seven of the donors were of unmixed Australian ancestry, according to their own accounts and also to their appearance. The bloods of fifty-four were collected on a visit to the Mona-Mona Mission, and the remainder of the samples was obtained at the Cairns Base Hospital. The blood was taken in 'vacunes' and arrangements were made for speedy transport with cooling on the way, so that they were examined in London less than ten days after they had been obtained in Australia. There was no visible hæmolysis. The bloods were sterile, and it is known from the experience of testing blood samples sent under similar conditions from Africa and Greece that the sickle cell trait can be demonstrated for at least two to three weeks after the arrival of the bloods in London. All samples were examined both by incubation with sodium-metabisulphite and with sodium-hydrosulphite[6,7]. None of the blood samples was found to show the sickle cell trait.

The examination of blood groups of Australian aboriginals is carried out so adequately in Australia that we felt it superfluous to extend our investigation into this field. However, to test the freshness of the samples and to verify the presence of the R chromosome in our particular group of aboriginals, Miss E. W. Ikin, of the Blood Group Reference Laboratory, kindly determined a number of blood group systems, and confirmed that the blood group distribution, which included the presence of the R_z chromosome, agreed with that to be expected from previous reports on the blood groups of Australian aborigin

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, October 5

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. S. F. Smith: "Surface Finish and its Measurement by Electronic Methods".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the LONDON SECTION, ROYAL INSTITUTE OF CHEMISTRY, in the Chemical Society's Rooms, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. A. J. E. Welch: "Recent Developments in the Chemistry of Metal Oxides".

Tuesday, October 6

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Papers on "Liquid–Liquid Extraction".

Wednesday, October 7

INSTITUTE OF FUEL (in the Lecture Hall, Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Dr. Harold Hartley: "The Domestic Appliance Industry and Fuel Usage". (The Melchett Lecture for 1953.)*

THE EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. James Shields: "Personality Differences and Neurotic Traits in Normal Twin School Children".*

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Discussion on "Destruction of Organic Matter". Mr. G. Middleton and Dr. R. E. Stuckey: "The Preparation of Biological Material for the Determination of Trace Metals. Part II. A Method for the Destruction of Organic Matter in Biological Material"; Dr. H. C. Lockwood: "Determination of Lead in Foodstuffs".

Thursday, October 8

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—General Meeting. Dr. K. A. Kermack: "An Ancestral Crocodile from South Wales"; Miss W. M. A. Brooke: "The Vegetation of Wet Districts of the Bolivian Andes from 10,000 ft. to the Snowline".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. Bishop: Inaugural Address as President.

Friday, October 9

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

TELEVISION SOCIETY (at the Cinematograph Exhibitors' Association, 164 Shaftesbury Avenue, London, W.C.2), at 7 p.m.—Mr. C. B. B. Wood: "Recording Television Programmes".

Saturday, October 10

INSTITUTION OF CHEMICAL ENGINEERS, NORTH-WESTERN BRANCH (joint meeting with the CHEMICAL ENGINEERING GROUP and the MANCHESTER SECTION of the SOCIETY OF CHEMICAL INDUSTRY, in the Reynolds Hall, College of Technology, Sackville Street, Manchester), at 3 p.m.—Mr. Norman Swindin: George E. Davis Memorial Lecture.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (Grade A) IN APPLIED SCIENCES at the Constantine Technical College, Middlesbrough, to teach applied sciences in craft courses having a biological and chemical bias—The Director of Education, Woodlands Road, Middlesbrough (October 10).

ASSISTANT (preferably with honours degree in science or agriculture) IN THE CHEMISTRY DEPARTMENT, for work mainly connected with plant nutrition and soils—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (October 12).

SENIOR LECTURER OR LECTURER IN PHYSICS at the University College of the Gold Coast—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (October 12).

LECTURER (with degree in electrical engineering, and able to teach up to final degree standard) IN ELECTRICAL ENGINEERING—The Principal, Wigan and District Mining and Technical College, Wigan (October 14).

DEMONSTRATORS (3) (with first- or second-class honours degree in chemistry) IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Liverpool (October 24).

PHYSICISTS (with H.S.C. (Science) or equivalent, and experience or interest in one of the following desirable: electronics, particularly as applied to counter circuits and recording of high speed transient phenomena; ultra high speed photography; electronic and mechanical instrumentation; general physics of shock waves; physical metallurgy) at Ministry of Supply Research Stations near Sevenoaks and Southend, for work chiefly concerned with physical and physico-chemical characteristics of detonation and associated phenomena—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.246/53A (October 24).

POLYMER CORPORATION RESEARCH STUDENTSHIP IN CHEMISTRY—The Registrar, University College of North Staffordshire, Keele, Staffordshire (October 31).

PRINCIPAL (with good honours degree and teaching experience in science, engineering or arts, and experience of administration with high degree of responsibility) OF THE NIGERIAN COLLEGE OF ARTS, SCIENCE AND TECHNOLOGY—The Secretary, Advisory Committee on Colonial Colleges, 1 Gordon Square, London, W.C.1 (October 31).

LECTURER (preferably with a special interest in some branch of applied mathematics) IN MATHEMATICS—The Registrar, College of Technology, Manchester 1 (November 2).

CHEMIST, RESEARCH OFFICER or SENIOR RESEARCH OFFICER (with honours degree in chemistry or equivalent, and research training or experience in physical or organic chemistry) in the South African Council for Scientific and Industrial Research, Bituminous Binder Research Unit, Pretoria, to carry out original studies on the weathering of tar and bitumen binders used in bituminous road surfacing materials, with the object of improving their durability and road performance, and supervise the analytical control work associated with the laboratories full-scale road work—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, November 3).

CHAIR OF MORBID ANATOMY tenable at St. Mary's Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (November 4).

UNIVERSITY DEMONSTRATOR (with honours degree in pure science or agricultural chemistry with specialization in soil science) IN SOIL SCIENCE—The Secretary, School of Agriculture, The University, Cambridge (November 7).

ASSISTANT DIRECTOR (graduate in engineering, physics, chemistry or microbiology, and experience of research in the preservation, processing and transport of food, preferably fish) AT THE FISHING INDUSTRY RESEARCH INSTITUTE, Cape Town—The Secretary, P.O. Box 1233, Cape Town, South Africa (November 16).

ABSTRACTOR (science graduate, and preferably with knowledge of textile technology, and capable of abstracting technical and scientific papers from foreign, particularly German, periodicals) IN THE INFORMATION DEPARTMENT, British Cotton Industry Research Association—The Director, British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester 20.

BIOPHYSICIST or PHYSICIST, a PHYSICAL CHEMIST, and a BIOCHEMIST (with honours degree and preferably with postgraduate experience) for work with a small research unit investigating problems concerned with new methods for detecting the location of enzymes in animal tissues and cells—The Secretary, Courtauld Institute of Biochemistry, Middlesex Hospital Medical School, London, W.1.

ELECTRICAL ENGINEERS (preferably graduates or Corporate Members of the Institutions of Electrical or Mechanical Engineers, and with sound training and appropriate experience) with the Central Electricity Board, Federation of Malaya—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M20/28770/TA.

ELECTRICAL ENGINEERS and PHYSICISTS, (*a*) Scientific Officer grade (with first- or second-class honours degree or equivalent in physics or light electrical engineering); (*b*) Experimental Officer and Assistant Experimental Officer grade (H.S.C. Science or equivalent), at the Ministry of Supply Radar Research Establishment, Malvern, for research and development work on radio and electronic equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.254/53A.

ELECTRONIC ENGINEERS and PHYSICISTS (with first- or second-class honours degree or equivalent in physics or electrical engineering), at the Atomic Weapons Research Establishment, Sevenoaks, Kent, for (*a*) Design, development and engineering of special electronic instruments, (*b*) Research, development and implementation of electronic equipment for special telemetry project, and responsibility during periodic field trials—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.255/53A.

ENGINEER (preferably with telecommunications degree) in the Ministry of Supply, Fort Halstead, Kent, to assist design and prototype production of electronic equipment in the audio, R.F. and U.H.F. bands—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.377/53A.

GEOLOGIST (with first- or good second-class honours degree in geology, and preferably with more than two years postgraduate experience) in Fiji, to assist the Senior Geologist to map, geologically in detail, mineralized areas in the Colony—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE/105/49/01.

GRADUATE (preferably with some knowledge of the steel industry) to undertake research on the flow of technical information in the steel industry—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "Information".

LECTURER and an ASSISTANT LECTURER (with special knowledge of cytology, genetics, ecology, taxonomy or anatomy) IN BOTANY—The Registrar, The University, Nottingham.

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with first- or second-class honours degree, preferably in psychology or social science, and two or three years research experience, and ability to deal with a wide range of subjects) IN THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH, Headquarters Office, for work on human factors in industry—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.309/53A.

SENIOR LECTURER AND HEAD (with professional and teaching experience, and preferably with experience in structural theory and design) OF THE DEPARTMENT OF CIVIL ENGINEERING—The Secretary and Registrar, The University, Southampton.

SENIOR LECTURER IN CHEMICAL ENGINEERING at the Technical College, Bradford—The Director of Education, Town Hall, Bradford.

SENIOR RESEARCH OFFICER or PRINCIPAL SCIENTIFIC OFFICER (with university honours degree, and special training and research experience in fuel technology or in applied chemistry, or equivalent qualifications) IN THE COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION, Coal Research Section, Sydney, N.S.W., to undertake investigations into the properties of coal with respect to the formation of gas, coke and chemical products upon carbonization—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway London, W.C.2, quoting 480/107.

SENIOR SCIENTIFIC OFFICER or SCIENTIFIC OFFICER (with first- or second-class honours degree in bacteriology or microbiology, or degree including chemistry and biology followed by postgraduate diploma in bacteriology) IN THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH, Water Pollution Research Laboratory, Watford, for research on bacteriological problems in work on pollution of rivers and treatment of water, sewage and trade wastes—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.308/53A.

SENIOR SCIENTIFIC OFFICER or SCIENTIFIC OFFICER (with first- or second-class honours degree in inorganic or physical chemistry) IN THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH, Water Pollution Research Laboratory, Watford, and subsequently at Stevenage, for research on the rates under different conditions, of reactions occurring in the polluted Thames estuary, including reduction of sulphates and oxidation of sulphides—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.477/53A.

SENIOR SCIENTIFIC OFFICERS and SCIENTIFIC OFFICERS (with first- or second-class honours degree in a scientific subject (including engineering) or equivalent) IN THE MINISTRY OF FUEL AND POWER, Chief Scientist's Division, London, for duties concerned with conceiving and developing novel sources and uses of fuel and power—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting E.259/53A.

TECHNICAL ASSISTANT (with some training and experience in topographical draughtsmanship and general cartography) IN THE DEPARTMENT OF GEOGRAPHY—Prof. Peel, Department of Geography, The University, Leeds

Gregory's "Notae in Isaaci Newtoni Principia Philosophiae".—Dr. William P. D. Wightman 690

ACADEMIC FREEDOM IN A DEMOCRACY

REFERENCE has been made in these columns more than once to the statement issued by the American Association of Universities on the rights and responsibilities of universities*. Their freedom—their duty to pursue the truth wherever investigation may lead—is extended also to the realm of teaching; there should be no curb on freedom of expression in the class-room. The university student should be exposed to competing opinions and beliefs in every field, so that he may learn to weigh them and to gain maturity of judgment. To curb such freedom of teaching, in the hope of avoiding criticism, would be to distort the true process of learning and to deprive society of its benefits.

In arguing here for the recognition and expression of honest differences of opinion, and that the university supplies a distinctive forum for such expression which should, moreover, provide the security which unorthodoxy may sometimes require, the Association joins other stout champions of dissent like Dr. J. B. Conant and Prof. A. Macbeath; but it does not fail also to insist that if there is a duty of utterance and a privilege of freedom to do so, there is also a duty of loyalty to professional ideals and to society. The word 'university' is historically a guarantee of standards, endorsing not the views of its members, but their capability and integrity. The scholar has a heavy responsibility to weigh the validity of opinions and the manner in which they are expressed, and to avoid public acts or utterances which may adversely affect his profession, his university or the general welfare. The greater the autonomy he enjoys through his position in a university faculty, the greater is his responsibility to the public.

With the more specific references of the statement to the position of the universities in the United States as regards the security and loyalty investigations we need here be no further concerned than to note that reliance is placed on public opinion to check the abuse of powers of legislative inquiry, and that the responsibility for academic discipline where necessary is regarded as one for the faculty itself. It is accepted that appointment to a university position and the retention of such an appointment involve not only professional competence but also the affirmative obligation of diligent and loyal citizenship. A scholar must possess integrity and independence, and in the Association's view any kind of clandestine or conspiratorial activity is precluded.

While the statement may go a little too far in its remarks about the duty of candour and the acceptance of conventions, it puts its finger on the essential difficulty in the employment of an avowed communist in a university. It is difficult, if not impossible, to reconcile adherence to communism and its demand for the surrender of the duty of independent criticism with loyalty to the professional ideal and the unflinching and impartial search for truth which mark the scholar. If a university teacher in his class-room becomes a protagonist of one opinion, silences criticism or impairs freedom of thought or expression, he forfeits, in the view of the Association, not only all university support but also his right to membership of a university.

---

* The Rights and Responsibilities of Universities and their Faculties: a Statement by the Association of American Universities, adopted Tuesday, March 24, 1953. Pp. 16. (Princeton, N.J.: Dept. of Public Relations, Princeton University, 1953.)

In this view the Association of American Universities is in line with Sir Walter Moberly; but none the less it does not countenance the indiscriminate condemnation of any member of a faculty who may be suspected of communist leanings. Unless he has violated a law, his discipline is solely a university affair and not a political responsibility, and while the statement claims no special privileges in law for university teachers it insists that they should not be subject to special discrimination. Such discrimination, if in the form of special loyalty tests applied to members of a university faculty but not to other people, does harm to the individual and even greater harm to his university and to the whole cause of education by destroying faith in the ideals of university scholarship.

In the face of such a firm—and by no means isolated—protest, it is not easy for a British observer to judge how far the loyalty inquiries in the United States have undermined public confidence there in the integrity and impartiality of the universities. Despite the implications of remarks on university education in the Labour Party manifesto "Challenge to Britain", there is as yet little reason to believe that academic integrity and independence in Great Britain are seriously doubted in any responsible quarters, though it is evident that public understanding of the reasons why academic freedom is so important is far from complete. Without, however, that general understanding, the universities can scarcely make their full contribution in public life to-day.

It was well expressed by the U.S. President's Commission on Higher Education: "A prime essential of a free society is academic freedom. Without it there can be no real profession of teaching or research. Pressure to bend or twist truth, to stay away from controversial issues about which the professor is competent to speak, and to avoid certain areas of inquiry, are not compatible with the ideal of professional integrity. A democratic society has a grave responsibility for maintaining free and untrammelled the avenues of communication". And it may be added that if a university is indeed to be not merely a place where the criticism and evaluation of ideas are continually being carried forward, but also where nonsense can be exposed for what it is, and the intellectual virtues rooted in sincerity of mind fostered and transmitted, a firm guarantee of academic freedom for the individual is essential.

Nor have the universities a more vital function to fulfil in the world to-day than this exposure of humbug and the keeping of public discussion uninhibited, searching, fair-minded and tolerant. Even more important than the direct contribution which individual members of a university may be able to make to the discussion of particular problems within their own special competence is the contribution which the university makes indirectly by supplying the community continuously with minds trained to handle public issues imaginatively, justly and impartially, as well as with technical knowledge and skill. It was apparent from the discussions at the recent Universities' Congress, particularly in that on higher technological education, that there is some concern as to whether the new education of this scientific age is good enough at producing the sound, rounded and cultivated minds that are so important.

"Nothing," said Sir Richard Southwell, in a recent address to the Royal Society of Arts, "could be more disastrous to our industries than deprival of our engineers-in-embryo of the wider outlook and the growth in tolerance that come from informal association with men of other disciplines"; but failure on the part of the university to-day to develop that outlook and toleration is not entirely due to excessive specialization. It can equally be due, as the University Grants Committee has noted, to the lack of cultural background in the home, and the increasing proportion of students who have no such breadth of cultural experience behind them as a good professional home of a generation or more ago provided makes it all the more important that the universities should explore urgently and assiduously the possibilities of making good this deficiency.

A prime purpose of the University College of North Staffordshire, under the late Lord Lindsay's guidance, was to experiment in the provision of men and women with a broad general training. Sir John Lennard-Jones, in his inaugural address delivered last May, made it clear that he is pursuing the experiment, and that this attempt to provide the intending scientist with a broad cultural background and at the same time to give students of the arts and social subjects some idea of the aims, methods and achievements of the scientist will be resolutely continued. It will be noted that in this address Sir John referred again to the importance of the university teacher, as a privileged member of society, demonstrating by teaching and example the ideal of the educated man. He, too, called for integrity of mind and fearless honesty in following the argument wherever it leads, irrespective of prejudice and preconceived ideas, for the recognition of essentials in a train of thought or discussion and the ability to reject the secondary or irrelevant, and for accuracy and clarity of exposition.

The responsibility, however, rests on professional associations and institutions as well as on the universities. Moreover, though it is on his own personal integrity and judgment that the professional man or scholar must rely when he takes his stand on some issue within his competence and resists any external pressure to warp or distort his judgment, it is, as Carr-Saunders and Wilson have pointed out, from within his professional organization that he will find the anchorage and support that may make his stand effective. Independent centres of reflexion, criticism and judgment are essential for the health of the community. With startling prescience Sir Michael Sadler wrote in 1901 in his special report "Unrest in Secondary Education in Germany and Elsewhere": "If a highly centralised State once gets a grip on the conditions of intellectual life, those who act on behalf of the State are apt to discourage freedom of discussion and what matters far more, freedom of social and educational experiment".

In this issue of academic freedom the position of the professional organization is, in fact, linked with that of the university. Freedom of utterance of criticism and discussion are for them the counterpart of academic freedom, and the more so as the universities follow Sir Hector Hetherington's plea and give sovereign place to the educational rather than the professional ideal. No matter how successfully the universities may foster the unforced, informal, invigorating education which comes from the mutual impact of minds of different ancestry and interest, it will rest with the professional institution to put the final sharpening edge on the professional experience of the graduate when he goes out to practise his skill in industry or elsewhere.

For the professional institution to exert its full influence, however, its integrity must command the same public confidence as that of the university. A professional institution, either corporately or through its individual members, may well have a public duty to pronounce upon technical or professional aspects of public affairs in which there may be acute controversy. To do so effectively it must command respect for its candour, sincerity and fairness of mind. It must manifestly confine its representations to matters to which its members are competent to give, and have given, serious and informed consideration, and must present fully and faithfully all the evidence relevant to a decision.

What is clear above all to-day is that the values which both the university and the professional ideal assert are precisely those most essential to the functioning of a democratic society which Sir Ernest Barker has described so clearly—a society in which the energies of personal freedom are restrained by mutual respect, which is based, therefore, on equality under a public law, the virtues of which include toleration, sincerity and humility of spirit and which functions by persuasion and discussion and accommodation as opposed to intransigence, rejecting all claims to dogmatic authority. The defence of academic freedom and of professional ideals and traditions is part of the defence of democracy itself.

PRACTICE OF ASSAYING IN THE SIXTEENTH CENTURY

Lazarus Ercker's Treatise on Ores and Assaying
Translated from the German edition of 1580 by Anneliese Grunhaldt Sisco and Cyril Stanley Smith. Pp. xxxiii+360. (Chicago: University of Chicago Press; London: Cambridge University Press, 1951.) 75*s*. net.

IN 1683 one of those large folios so favoured by seventeenth-century writers was published in London, with the title "Fleta Minor". The author was Sir John Pettus, and his book was the first translation into English of Lazarus Ercker's famous treatise on the assaying of metalliferous ores, which had first appeared, in German, at Prague in 1574. Pettus was a deputy governor of the Society of the Mines Royal, and had published, in 1670, "Fodinæ Regales", a history of the chief mines and mineral works in England, Wales and Ireland. It is probable that his translation of Ercker's work, in later German editions entitled "Aula Subterranea", was made originally for the Society of the Mines Royal, but its appearance in print seems to have been due to the interest taken in the matter by the Royal Society. Preparations for publication were actually carried out in the Fleet prison for debtors, in which Pettus had the misfortune to spend the closing years of his life; hence the title and the dedication to, among others, the Warden of the Fleet.

"Fleta Minor" is now an uncommon book, and, in any event, it does not appear that Pettus was specially skilled in the German language, so that the issue of a new and scholarly translation is welcome. This has been prepared through the happy collaboration of a linguist, Mrs. A. G. Sisco, and a distinguished metallurgist, Dr. C. S. Smith, director of the Institute for the Study of Metals in the University of Chicago. It may be remembered that a similar joint effort on the part of Dr. Smith and Dr. Martha T. Gnudi gave us the first complete translation into English of another metallurgical classic, Biringuccio's "Pirotechnia" (*Nature*, 151, 569; 1943); and that Dr. Smith and Mrs. Sisco also collaborated in producing translations of two other well-known sixteenth-century books, one on mining geology and the other on assaying ("Bergwerk und Probierbuchlein". New York: American Institute of Mining and Metallurgical Engineering, 1949.

Ercker signs the preface of his book as chief superintendent of mines and comptroller in the kingdom of Bohemia, and dates it from St. Annenberg (Annaberg) in the Saxon Erzgebirge, a district for centuries a centre of mining activity. He lived in an age when the transition from ancient to modern science was just beginning, though upwards of two centuries were to elapse before chemical and physical theory was sufficiently advanced to have any practical application in assaying, which was then, and for a very long time afterwards, purely an empirical art. Ercker, there is reason to believe, was a man of judgment, and well informed about his subject. He was not an alchemist, but an accurate recorder of facts. His observations were made from the point of view of their utility in metallurgical practice, without the intention of theorizing about them. It is this that gives his book its particular value. The esteem in which the book was held may be surmised from the fact that eight editions in German appeared between 1574 and 1736, that the original English translation was twice reprinted, and that a Dutch translation was published as late as 1745. Bibliographical particulars and reproductions of the title pages of all these editions are given in an appendix to the new translation.

If this book is read in conjunction with the Hoover translation of Agricola's "De Re Metallica" and the English edition of Biringuccio's "Pirotechnia" referred to above, it is possible to form a complete and detailed picture of sixteenth-century metallurgical practice. The interest of Ercker's account is enhanced by the illustrations of the processes described, about forty in number, and these have been very well reproduced in the translation. The text is also enriched by a historical introduction by Dr. Smith, the bibliographical appendix already mentioned, a short account of the life of Sir John Pettus (reproduced from a manuscript in the possession of one of the translators), a note on the system of weights and measures used by Ercker, and an extensive list of the reference works used by the translators in preparing this edition.

It may come as a surprise to readers versed in modern assay practice to find how little change there was in assaying techniques for three centuries following Ercker's time; and even to-day, Dr. Smith states, the assay of gold and silver ores is conducted in almost exactly the same manner as that described by Ercker, with similar implements. The book has, however, a wider interest, for the light it throws on the practical knowledge of chemistry that existed among these old assayers, often quantitative as well as qualitative. They were establishing a tradition of accurate measurement and, at the same time, accumulating data later to be used in the formulation of chemical theories.

Here, then, is a book which should appeal not only to the student of early technology, but also to those interested in the development of chemistry and metallurgical practice. It is an important addition to the list of definitive translations of early scientific classics. Finally, a word of praise is due to the publishers, the University of Chicago Press, whose use of large clear type and fine paper has resulted in the production of a very attractive book.

LIFE-HISTORY OF MARINE FAUNAS

Zoogeography of the Sea

By Sven Ekman. Translated from the Swedish by Dr. Elizabeth Palmer. (Text-Books of Animal Biology.) Pp. xiv+417. (London: Sidgwick and Jackson, Ltd., 1953.) 42s. net.

MARINE zoogeography is an exacting but absorbing aspect of oceanography. A critical awareness of the extent of marine investigations and an understanding of systematic zoology are first needed. But the zoogeographer should have a good knowledge of physical oceanography, climatology, submarine geology and palæontology. In Prof. Sven Ekman's "Tiergeographie des Meeres", published in Leipzig in 1935, these sciences were brought to bear on the problems of distribution: the well-reasoned synthesis which emerged needs little introduction to marine biologists.

In this very welcome English edition Prof. Ekman has revised the text and brought it up to date, and Dr. Elizabeth Palmer has made the translation from the Swedish. Here and there a sentence reads awkwardly or quaintly; but the main impression is that justice has been done to Ekman's lucid writing. There are a number of printing errors, although none is serious. On p. 368 *Japetella diaphana* is referred to as a squid: it is an octopod.

Since 1935 there have been many developments in oceanography: about a quarter of the bibliography (598 references) consists of papers published during or after that year. Reports on the work of expeditions have greatly added to knowledge of deep-water zoogeography, particularly those dealing with the investigations of the *Dana*, *Meteor*, *Discovery II*, *William Scoresby* and *Mabahiss*. Russian work in the Arctic and in the seas of the North Pacific has thrown new light on the relationships of the marine faunas. The ecological surveys of the intertidal regions of South Africa and North America by Stephenson and his colleagues have clearly revealed the faunal components and their correlation with hydrological conditions. These more recent investigations and many others have become integral parts of the book, together with relevant developments in physical oceanography.

The assimilation of recent research has also led to a more objective approach. In the English edition there is a greater precision of method, partly seen in the increased use of analytical tables giving a measure of the degree of endemism of a fauna and other features of its composition. Ekman is careful to add that the tables also reflect present limited knowledge. But within the limitations, the tables are handled convincingly. Quite the most interesting sections—and these make up much of the book—develop from the statistical comparisons of faunas and a disciplined yet flexible use of the findings of related sciences in tracing relationships. Ekman sees a fauna as a living unit which changes with time. "The attempt, by growing refinement of method, to find out more and more of the life history of these faunas provides a particular stimulus for the zoogeographer."

Oceanography has grown rapidly since the Second World War; and the publishers, editor and author are to be thanked for the timely production of this valuable book. The "Tiergeographie des Meeres" has been a stimulating guide to many marine biologists; the "Zoogeography of the Sea" will extend this influence and provide an even broader background against which specialists can view their work. In so doing they are likely to agree with Prof. Ekman ". . . that even today, when an ever increasing specialisation is often a condition of progress, there are still sciences left which find in the opening up of frontiers and in the collaboration with other sciences the conditions for their own progress".

N. B. Marshall

CHEMOTHERAPY OF MAN AND ANIMALS

The Sulphonamides and Antibiotics in Man and Animals

By Dr. J. Stewart Lawrence and Prof. John Francis; with the assistance of Dr. Arnold Sorsby and Dr. Philip G. Scott. Second edition. Pp. xii+482+10 plates. (London: H. K. Lewis and Co., Ltd., 1953.) 42s. net.

THE discovery of the sulphonamides and antibiotics has revolutionized medical practice. Whereas sixteen years ago chemotherapy was restricted to malaria, amœbic dysentery, syphilis and a handful of tropical diseases, there is now scarcely a single bacterial infection which has not at some time been amenable to treatment. Dr. J. Stewart Lawrence and Prof. John Francis and their colleagues have set themselves the difficult task of providing a guide to the use of these new drugs in the treatment of bacterial infections in man and animals. The plan which they have adopted in this book, which is the successor to the first edition dealing with sulphonamides, is, after a discussion of general principles, to pass to the sulphonamides in general and individually, and from there to a separate chapter on drugs used for the treatment of leprosy and tuberculosis, the sulphones, thiosemicarbazones and *para*-aminosalicylic acid. Antibiotics in current use, penicillin, streptomycin, neomycin, chloramphenicol, and aureomycin and terramycin are considered next, and most of the remainder of the book is devoted to a discussion of the clinical use of all these agents.

To cover so much ground in a single volume requires careful designing and care in the selection of material, and the authors have succeeded in producing a clear and readable guide to modern practice. The section on veterinary chemotherapy is an interesting account of this young but rapidly expanding field, and is a reminder that the value of the sulphonamides and antibiotics is by no means confined to the treatment of human patients.

In one respect the authors have been handicapped in a way which is almost inevitable. The position of the sulphonamides is established, but new antibiotics are being discovered, and there is still much to be learnt about current ones, and much may happen in the interval between writing and publishing a book. This is perhaps most noticeable here in the sections concerned with bacterial resistance. Recent experience has shown that the development of resistance by bacteria to chemotherapeutic agents is a pressing problem, which more than anything else threatens to nullify the value of the majority of drugs which we now have, and for which a solution is urgently needed. In future editions the effect of this change, and particularly the increase of penicillin-resistant staphylococci, will require restating.

R. A. SHOOTER

THE ASTRONOMICAL OBSERVATORIES OF JAI SINGH

Maharaja Sawai Jai Singh II of Jaipur and his Observatories

By M. F. Soonawala. Pp. x+44. (Jaipur: Jaipur Astronomical Society, 1952.) 2 rupees.

THE astronomical observatories built by the Maharaja Jai Singh II at Delhi, Jaipur, Ujjain and Benares during the second quarter of the eighteenth century are familiar to visitors to these cities. A fifth observatory, which he built at Mathura, no longer exists. The great masonry instruments, generally similar in design at each of the observatories, have no counterpart elsewhere. They are impressive and curious. Jai Singh had the mistaken idea that large fixed instruments of great stability were necessary in order to obtain accuracy; he thought that with small movable instruments the errors of graduations, the wear in pivots and bearings, and the instability of mounting must result in appreciable errors of observation.

Full descriptions of the observatories, and of the design and principles of the instruments, have been given in G. R. Kaye's excellently illustrated monograph, "The Astronomical Observatories of Jai Singh", published by the Archæological Survey of India in 1918. The volume under review has been published by the Jaipur Astronomical Society, which was founded in September 1948; it has a foreword by the Maharajah of Jaipur.

Jai Singh lived during a very disturbed and troubled period of Indian history, and it is remarkable that in such a time he was able to concern himself with astronomy and to build five observatories. In this book an account is given of his life and of the astronomical contacts between India and Western Europe. This is followed by an elementary explanation of the principles of spherical astronomy which are needed for understanding the design of Jai Singh's instruments. The instruments themselves are described in a final chapter, in which photographs of many of them are reproduced.

The Jaipur Astronomical Society is to be commended for the publication of this moderately priced guide. It will help visitors to these old observatories who have no knowledge of spherical astronomy to understand the design and use of the instruments; but it has also a wider interest as an account of a strange side-track in astronomical instrumentation.

HAROLD SPENCER JONES

ENGINEERING ASPECTS OF ACOUSTICS

Musical Engineering

An Engineering Treatment of the Interrelated Subjects of Speech, Music, Musical Instruments, Acoustics, Sound Reproduction and Hearing. By Dr. Harry F. Olson. Pp. ix+369. (London: McGraw-Hill Publishing Co., Ltd., 1952.) 55*s*. 6*d*.

A NUMBER of books have appeared in recent years the purpose of which is to expound to musicians the recent notable advances in acoustics. Their content has been mainly physics, perhaps with an admixture of physiology; but the present volume is unusual in that, as the title indicates, it purports to deal with the subject as a branch of engineering and so emphasizes those parts of technical acoustics in which are comprised building acoustics and sound reproduction. Besides this, the fundamentals of sound, vibrating systems, speech and hearing are covered in outline.

Less usual in books on this subject, there is a brief description with typical acoustic spectra of all the modern orchestral instruments, but surprisingly—because this is where the author could have made his text distinct from that of 'non-musical' books on applied acoustics—little or no mention of the considerable amount of research done in Europe and the United States in the past twenty-five years on the physics of the functioning of such instruments. Considering that in other sections the information is quite up to date, a similar treatment might have been expected of the advances in this field, which at the present time are having their effect in the musical instrument industry. One would have liked, too, more than the four pages which the author feels sufficient to cover electrophonic instruments, 'electronic organs', and the like.

From the point of view of the scientist interested in music, the presentation is excellent. The treatment is non-mathematical, mainly by clear illustrations, while analogues in alternating-current engineering (circuit diagrams) are given whenever possible.

How far musicians without scientific training will be interested in a book of this type is difficult to say; but one imagines such people will still look for technical guidance to the standard works on harmony and orchestration. Indeed, Dr. Olson and his publisher are not helped by the artist of the wrapper, who in a short four-note specimen of musical notation has perpetrated an equal number of musical solecisms, surely a record!

E. G. RICHARDSON

AN INTERNATIONAL LABORATORY FOR NUCLEAR RESEARCH

ON July 1, a Convention was signed in Paris for the establishment of a European Organization for Nuclear Research. Representatives of twelve European nations took part in the ceremony, and the Convention will take effect when the signatures have been ratified by the Governments of Switzerland, the host country, and six other nations. In the words of the Convention, the purpose of the Organization is to "Provide for co-operation among European states in nuclear research of a pure scientific and fundamental character and in research essentially related thereto. The Organization shall have no concern with work for military requirements and the results of experimental and theoretical work shall be published or otherwise made generally available". This achievement has been brought about through the initiative of Unesco, which, at its general conference in Florence in 1950, instructed its director-general "To assist and encourage the formation and organization of regional research centres and laboratories in order to increase and make more fruitful the international co-operation of scientists in search for new knowledge in fields where the effort of any one country in the region is insufficient for the task".

During an initial survey, the particular need appeared for joint action in nuclear research among European countries, for the modern equipment required is often very costly. Although work with cosmic rays is relatively inexpensive to carry out and is extremely fruitful in results, its role is to make a preliminary survey of the high-energy field. Many important findings which are made by it can only be followed up if high intensities of high-energy particles are available. These high intensities can be produced in a perfectly controllable manner with modern high-energy particle accelerators, but these are extremely costly and may be quite beyond the resources of many countries.

The European Council for Nuclear Research (C.E.R.N.) was therefore established in May 1952, to work out plans for co-operation in this field. One of the Council's first acts was to arrange an international scientific conference in Copenhagen during June 1952. Many eminent nuclear physicists were present, including a number working in the field of cosmic rays. The state of knowledge at that date was examined in order to obtain guidance upon the main problems requiring further investigation. After the conference, four study-groups were set up by the Council. The first was to consider the design of a 600-MeV. synchrocyclotron, the second the design of a proton synchrotron for energies greater than 10 GeV., the third was to concern itself with theoretical studies of interest to the Council and the promotion of other forms of co-operation in nuclear physics, and the fourth was to work out plans for a laboratory.

The 600-MeV. synchrocyclotron was chosen because as a machine it is relatively straightforward to design and build, and yet when completed it will provide a laboratory source of mesons and high-energy protons for European physicists who have not had previous access to them. It should be practical to complete this machine in a few years, and much in advance of the time likely to be required to build the proton synchrotron. In the course of its development it will provide experience in running a co-operative research programme with a project the technical problems of which are relatively straightforward. When it is completed, physicists will, in the course of its use, become familiar with the techniques necessary when working with high-energy particles, and so should be ready to make full use of the big machine with the minimum of delay when it is completed.

The proton synchrotron is in an entirely different category, for an energy greater than 10 GeV. is well beyond that of the biggest machine now being built in the United States, and so when completed it should make available new fields of work only investigated previously by workers with cosmic rays.

The basic programme now envisaged for the Organization is the construction and organization of an international laboratory for research on high-energy particles, including work on cosmic rays, and the organization and sponsoring of international co-operation in nuclear research including co-operation outside the laboratory.

The laboratory will be located at Geneva, Switzerland, on ground offered by the Government of that Canton. The site is approximately 600 metres square and adjoins French territory about three miles north-west of the town. The main tools of the laboratory will be the two high-energy particle accelerators which have been studied.

The design of the synchrocyclotron is already well advanced, and its construction can be started quickly once the Organization is established. The machine will be used for neutron and proton studies up to 600 MeV., meson studies up to 300 MeV., radiochemistry, and possibly production of more than one π meson in some nuclear collisions. The cyclotron magnet will have a pole diameter of 5 metres and will weigh 2,500 tons. It will be excited by two coils weighing 180 tons with a power consumption of 700 kW. to give a magnetic field at the centre of 20,500 oersteds. Between the poles will be mounted a stainless-steel vacuum chamber containing the accelerating electrodes. The machine is primarily designed to accelerate protons; but provision will probably also be made for the acceleration of deuterons and α-particles. For protons, the radio-frequency at the start of the acceleration will be 31 Mc./s. and the frequency change required will be 2 to 1. The frequency repetition-rate will be 50 cycles per second. Considerable attention has been given to the experimental facilities to be provided with this machine. Collimated beams of protons, neutrons and mesons will be available. There will be one experimental room for neutron and π-meson studies. Neutrons of energies up to 600 MeV. will be available at an estimated flux of approximately 10^5/cm.^{2}/sec., and the energy of the π-mesons will be up to 350 MeV. with an estimated flux of 10^3/cm.^{2}/sec. In a second experimental room, the extracted proton beam will be available with a maximum energy of approximately 550 MeV. and a flux of 10^7/cm.^{2}/sec.; π^+ mesons will also be available in this room up to an energy of about 200 MeV., again with a flux of approximately 10^6/cm.^{2}/sec. Thick shielding walls will separate both experimental rooms from the cyclotron.

Plans for the proton synchrotron are not so far advanced. The target energy for it has been set at not less than 10 GeV.; but it seems from the design study that 20 GeV. or higher will be achieved. Confidence that a proton synchrotron for this energy region can be built has been obtained from the success with which other large proton synchrotrons such as the Brookhaven cosmotron have been operated, as well as from the design study which has been in progress for the past year. This study was upon a machine to use the alternating-gradient focusing principle announced by Courant, Livingston and Snyder in 1952[1]. In any synchrotron the particles being accelerated perform vertical and radial oscillations within the annular vacuum chamber. The amplitude of these oscillations determines the required cross-section of the annulus and hence the size and cost of the magnet providing the guiding and focusing field. With a conventional machine, this magnetic field is made to fall off approximately linearly with radius, so that $\frac{\partial H}{\partial r} = -n\frac{H_0}{r_0}$, where n is a constant such that $0 < n < 1$, H is the field at radius r, and H_0 is the field at the particular radius r_0. When the condition $0 < n < 1$ holds, the particles being accelerated are acted upon by relatively weak focusing forces in both vertical and radial directions. In an alternating-gradient focusing machine, it is proposed to construct the magnet in a number of sectors and to make $|n| \gg 1$ with positive and negative values in alternate sectors. The forces acting upon the particles will then be strongly defocusing in the radial direction and strongly focusing in the vertical direction for sectors with positive values of n and vice versa. Courant *et al.* showed that the net effect upon particles passing around a machine constructed in this way would be a strong focusing action in both directions. This offered the possibility of achieving a reduction in both the vertical and radial dimensions of the aperture simultaneously.

The new principle has required a very careful design study, for as well as its important advantage, it also has inherent in it certain definite limitations which have had to be understood, and which will have to be taken into account in designing the machine. The limitations arise from the fact that the strongly focused particles are made to perform oscillations of small wave-length. These oscillations are very sensitive to small irregularities in the magnetic field whether they are due to mechanical or electrical causes, and consequently dangerous resonances can occur. The design study has had to take into account the practical considerations of achievable accuracies in constructing various parts of the machine, and determine how much advantage can be taken of the alternating-gradient focusing principle, that is, what should be the value of n. The relative importance of variations in each of the main design parameters has been worked out, and several possible designs obtained for machines of 30 GeV. energy with apertures less than ± 10 cm. and n's in the region of 100–1,000. A magnet weight of less than 10,000 tons seems practical with a manufacturing tolerance on the position of the equilibrium orbit of 0·020 in. However, more information is required upon the mechanical and magnetic tolerances achievable in the manufacture and measurement of magnets with various values of n and different apertures before a final choice of parameters can be made. Investigations are being carried out to obtain this information. Other problems in connexion with the machine, such as the design of the radio-frequency system and of the injector, are also being studied. It will be one of the major tasks of the new laboratory in its initial stages to complete this study and, with the help of industry, carry through its development and construction. It is estimated it will take six years to build, requiring a total staff of about a hundred scientists, draughtsmen and technicians, and will cost approximately 55 million Swiss francs. The plans for this machine envisage it being installed in a trench-type building below ground, with a thick roof over the trench to provide protection for the staff and reduce radiation in the main laboratory buildings to an acceptable level.

To make full use of the possibilities offered by these two accelerators, it will be necessary to gather together staff with specialist knowledge in several different fields. The present plans envisage a strong theoretical group which will work in Copenhagen for some time to come. It will carry out fundamental studies and take part in the planning and interpretation of the experimental work. A chemical department will be required for radiochemistry and to provide any analytical techniques required; and specialists in electronics and instrumentation for the design of experimental apparatus, and a central drawing office and workshop, will be necessary, in addition to the staff of nuclear physicists.

The architectural planning of the laboratory is well advanced. The main features of the accelerator buildings are entirely determined by their physical characteristics and functional requirements. For the laboratory it is proposed to construct single-story buildings with basements, which should allow great flexibility in detail, facilitate movements between laboratories and reduce radiation interference between different experimental installations. A unit method of construction is to be adopted, and careful attention has been given to the mode of distribution of services and the method of construction of partition walls to allow great flexibility in the internal arrangements. Present plans are for a main building with a total floor area of about 5,000 sq. m. available for the use of the scientific and technical staff; 2,500 sq. m. for lecture rooms, restaurant and administration, and a main workshop of 1,000 sq. m. floor area.

The construction of all the buildings and the arrangements of the site are expected to take three years and to cost about 23 million Swiss francs. The cost of all the activities, including construction and installation, during the first seven years is estimated at 120 million Swiss francs. The funds will be provided by the member States on a relative scale based on their average net national incomes; but no one State will pay more than 25 per cent of the total.

D. W. Fry

CYBERNETICS

DURING the recent meeting in Liverpool of the British Association, a joint symposium was formed by Sections J (Psychology), A (Physics) and I (Physiology), under the general title of "Cybernetics". Under the chairmanship of Prof. Ross Ashby, three papers were read and discussed: "Organisms and Mechanisms—an Introductory Survey" (Dr. Colin Cherry), "The Impact of Information Theory on Psychology" (Dr. W. E. Hick), and "On Comparing the Brain with Machines" (Dr. D. M. MacKay).

In his introductory paper, Dr. Cherry referred to the origin of the word "La Cybèrnétique" as being due to André Ampère who, in his attempted classification of human knowledge (1834), defined the concept as 'the science of government', taking the word from κυβερνητης, meaning 'a steersman'. Government, whether it means the administration of a country, or the control of our own personal actions, bears some analogy to the steering of a ship. It implies a stabilized directing on to a definite course, or goal-directed activity. Our modern concern with cybernetics represents, Dr. Cherry stressed, a revival of an intense interest of the seventeenth- and eighteenth-century philosophers, namely, the comparison of machines, human beings and social bodies—but with some essential differences. Descartes, who was a focus of such interest, argued in extremely vague philosophical terms; nowadays we are using mathematical analysis and, furthermore, we have techniques for constructing actual machines. Some machines show action which simulates closely certain aspects of human behaviour, mental and physical. How far may such machines go, if only in principle, and what is the purpose of such mechanistic description?

Popular language suggests we readily lean towards mechanistic analogies; we speak of 'the man at the helm', or again, of a man 'running off the rails'. But such metaphors do not form true scientific statements. Our modern interest, however, is not a simple return to the mechanistic–vitalistic (man or machine?) controversy of Cartesian dualism—not in philosophy so much as in physics. Questions such as 'Can a machine think?' are more profitably interpreted as 'What aspects of psychology may validly be discussed in the language of mathematics and physics?' (for example, 'thinking', 'learning', 'recognizing'?).

Modern machines which have self-stabilizing or goal-directed action and which show some similarity to human behaviour are plentiful, and a great body of mathematical analysis has been constructed. These machines are conveniently divided into two classes, exhibiting respectively body-like and mind-like behaviour. The former includes the so-called servo-mechanisms or automatic controls, and the latter relates to computing machines, the so-called 'electronic brains' (though if such science fiction images are necessary, 'electronic brain-extensions' may be preferable).

One idea which runs like a thread through the pattern of relevant studies is the idea of 'information'; information circulates through servo-mechanisms, calculating machines, and all communication channels, and again in the nervous system; it is manifest in human social institutions and systems. But 'information', like 'language', is a many-sided concept; Dr. Cherry directed attention to three aspects, each of which is concerned in the relation of cybernetics to psychology. First, and most important, selective-information refers to the correct selection of signal-elements or signs from a given set (letters, words or other signs, purely at syntactic level, but without regard to their designata); this is the concern of statistical communication theory (and, in a broader sense, of information theory), which sets up a precise measure of selective-information content of messages in terms of the statistical rarity of the signals or signs. Secondly, there is the semantic information which emerges in some cases (involving humans), where the signals are regarded as 'meaningful'. Finally, there are the pragmatic aspects, or those aspects of messages which convey information to a specific recipient and which affect his personal response. Dr. Cherry ended with a brief description of the measure of selective-information content, and sounded warnings of the pitfalls which surround anyone who attempts to 'apply' information theory outside its legitimate sphere.

The second speaker, Dr. W. E. Hick, illustrated a number of ways in which some of the concepts of this theory may be employed, quite legitimately, in practical psychological studies. From this point of view the organism is regarded as a 'black box' to which stimuli are applied, and the responses of which are observed. The 'black box' is here regarded as if it were performing the dual role of communication channel and code-changing transducer—*as if* the organism were a channel along which information flows. From this point of view, a natural descriptive system for those aspects of behaviour which may be described statistically is provided by information theory.

Very broadly, such analysis has been applied in three fields of experimental psychology: (1) hearing, language and speech; (2) reaction times; (3) learning.

Dr. Hick referred to the value of having a precise theory and measure of information when working in these various fields; descriptive or qualitative results may then be made quantitative, construction of experiments may be suggested, and their results may more readily be interpreted.

It is essentially the selective aspect of information which is concerned here, and not the semantic or pragmatic. This may seem strange, in a psychological context, but is a logical consequence of the 'black-box' point of view of regarding the organism as if it were a communication channel. But it must also be remembered that it is only this selective aspect which has as yet been based on a solid foundation of mathematics, and it is only the selective-information content of signals which may be measured quantitatively.

Illustrations were given by Dr. Hick from these three fields of experimental psychology, showing how a human 'black-box' behaves, in comparison to a communication channel—inasmuch as an information theory description may be applied to both. For example, in the first field, the stimuli (or 'messages') applied to the input of the 'black-box' may be spoken words, as in studies of speech recognition. In the second, the stimuli may be represented by successive selections of visual signals from a simple alphabet of signals, to which the subject is required to respond in some prearranged manner; then the relation between the subject's times of response and the errors he makes is shown to bear direct analogy to the properties of a simple communication channel—

in terms of the established measure of selective information-rate. The interpretation of such experiments, and others of like kind, is that, under a considerable variety of error-making conditions, the rate of selective-information in the human 'black-box' channel remains substantially constant. Dr. Hick gave a number of illustrations of such experiments, involving stimuli and responses of several different forms, and of extensions of the method to apply to an alphabet of signal-stimuli having unequal (objective) probabilities of occurring. He afterwards discussed these experiments, and their interpretations by the selective-information-content measure, in relation to other studies of reactions, emphasizing at the same time that the common idea of 'reaction-time' as a kind of constant, so frequently employed in tests for drivers and air pilots, is grossly inadequate. Dr. Hick ended his lecture by emphasizing that his experiments consisted purely of observations of behaviour and that, where probabilities were mentioned, they were objective, relative frequencies; nevertheless, he suggested, information theory has further value for psychology in that it provides a number of general concepts and terms which may aid discussion, at the purely subjective levels—though care must be taken to distinguish such subjective inquiry from direct, quantitative applications of information theory to behavioural psychology.

The last speaker, Dr. D. M. MacKay, distinguished three different ways in which brains are often compared with machines, for three different purposes. The first is the popular comparison between brains and existing machines, notably electronic digital computers. It is a relevant comment that such machines are deliberately designed not to imitate the brain in most of its more characteristic functions; on the contrary, they may be said to take over some of the more machine-like functions of the mind. The second concerns the question as to whether we can ever design an artefact ('artificial mechanism') to imitate any specified aspect of human behaviour; for example, to frame novel hypotheses or (notoriously) to write sonnets.

But the third manner of brain/machine comparison to which Dr. MacKay referred really formed his main theme: Can we build a model working internally on the same principles as the brain? Such may not be an actual engineered machine, but a conceptual model, conforming to all conditions demanded by present knowledge, broad though they be, and having as its purpose the setting up of a description not in the distinct languages of psychiatry, or physiology, or anatomy, but in language common to all these; to provide working links between these various fields. The language of information and control theory promises to be of value in this move toward unification of concepts because, in a sense, it belongs to both the psychology field and the domain of direct physical observation (physics, physiology . . . 'mechanism'). The theoretical characteristics of such a model may then be checked against observation of the brain in action, the discrepancies yielding information towards refining or replacing the model; and so repeatedly, by the usual inductive–deductive procedure. It is important that such models, or descriptions, should not only 'work' in the manner of a normal brain, and meet all functional tests in a similar way, but also that they should 'go wrong' likewise—though Dr. MacKay stressed that this is very different from naively attributing mental illness to electronic computing machines that break down.

A further requirement of the model is that, like the brain, it must have been capable of 'growing that way'; such consideration has led to investigations of the possibilities of self-organizing statistical models—models in which the various elements not only are interconnected more or less randomly, but which also themselves function indeterministically to some controllable extent. Such a model should be capable of adjusting the rules of its activity according to the degree of success it attains, by adjusting the relative probabilities of different patterns of activity. Dr. MacKay elaborated upon such a model, describing how, given some positive indication of success or failure, it could continually improve its 'goal-seeking' activity, and "grope its way more and more quickly into a pattern of activity to 'match' any incoming patterns that persisted in occurring".

Finally, Dr. MacKay dealt with questions of purpose. Such theoretical models are intended, he stressed, as research tools. They represent a method of describing 'the thinking process' in disciplined language, suitably objective as to assist the physiologist, yet not divorced from psychiatric reality, so as to permit further assistance in diagnosis, study and treatment of mental illness.

Such work is so often misinterpreted as an attempt to depose man from his special position; man would be 'nothing but' a machine, we often hear, if the brain is described in physical terms. The fault with such reductionist argument, as Dr. MacKay stressed, lies not in the possible incompleteness of the description, but in confusion between two distinct language-systems. Models of the brain form descriptions in observer-language—a set of directions by which, for example, replicas can be made; but a man's personal experience, or rather his statements about his experience, are in actor-language. Questions of personal decision-making, or questions of responsibility, simply do not form part of the brain-model because they cannot be framed in observer-language. However great our understanding of brain structure and functioning, however accurate the model, we none of us are one jot relieved from responsibility for our actions.

The discussion which followed centred mainly around the different uses of the words 'model', 'artefact', or 'mechanism' in such contexts. In response to one speaker who asked if real working models had actually yet been made, Prof. Ross Ashby gave a brief account of his 'homeostat' model, and of its behaviour.

E. Colin Cherry

UTILIZATION OF DIGITAL COMPUTING MACHINES

At the recent meeting in Liverpool of the British Association, Section G (Engineering) held a symposium on the utilization of digital computing machines in engineering and industry. Prof. F. C. Williams, of the University of Manchester, opened the meeting. Before introducing the main speakers, he said that the object of the session was to strip the 'electronic brain' of some of its glamour and to present it to engineers in its everyday shape, which is that of a potentially powerful new tool to aid the solution of engineering design problems. Although at present this tool is in an early stage of development, it is none the less already capable of revolutionizing design procedures—for example, by the rapid analysis of a large number of trial designs of turbine shafts or steel frameworks.

Dealing with the machine at the University of Manchester, Prof. Williams said that it originated from the joint initiative of himself and Prof. M. H. A. Newman, of the Mathematics Department. Although the machine was originally built to gain experience in design techniques, it soon became apparent that it is capable of handling a volume of work far in excess of the University's needs, and for this reason it was made available to other universities and to industry. This use of the machine by outside organizations has increased rapidly and, what is perhaps more important, those organizations which have started to use the machine have found themselves calling upon its services to an increasing extent as their experience of its potentialities increases. The University does not undertake the solution of problems, but instead trains representatives of other organizations in the use of the machine and afterwards makes the machine available to them. The period of training is about two or three months.

On the question of reliability, Prof. Williams said that, at the present stage of development, machines are serviceable for about 80 per cent of the time, and this is quite sufficient to enable them to be used as the basis of a computing service run on business lines. As in the case of human computers working with desk machines, electronic machines are liable to make transient mistakes, and results should be checked, also with the machine, in the usual way. However, because of the high speed of the machine, a fault-free run of several minutes corresponds to less than one mistake per week by a human computer. Finally, Prof. Williams stressed the ease with which digital machines can be switched from one problem to another. It simply requires a new set of instructions, which can be 'fed' into the machine from punched tape or cards in a few seconds.

Prof. Williams then introduced the other speakers: Mr. R. K. Livesley, of the Computing Machine Laboratory, University of Manchester, and Mr. G. G. Alway, of the Mathematics Division of the National Physical Laboratory, Teddington.

Mr. Livesley described first the general principles on which electronic digital computers are based. The most important fact about these machines, he said, is that they carry out calculations according to a pre-arranged sequence of coded instructions. Once this sequence of instructions (known as the 'programme') has been prepared, the computer carries out the calculations automatically. It is the job of the machine user to prepare the programme for his particular problem, and this means that he has first to decide in detail the sequence of arithmetic operations to be performed, and then translate this scheme into language understood by the machine.

It was emphasized by Mr. Livesley that, once the programme has been perfected, it can be used unchanged for different sets of numerical data. Thus a programme is very similar to a mass-production jig—both are capital investments which can be used an unlimited number of times. Like the machine tool to which the jig is attached, an electronic computer is most productive when engaged on repetition work—it is seldom worth while making either a jig or a programme if it is to be used only once. Such repetition work is very common in engineering calculations. Most of the numerical work associated with designing is concerned with the analysis of alternative layouts, the only difference in the calculations being the actual numbers occurring.

To illustrate the use of digital computers in design work, Mr. Livesley described four programmes developed for use with the Manchester computer. These cover the calculation of the natural frequencies of shaft systems in torsional and in lateral vibration, the design of certain types of cam, and the analysis of rigid-framed building structures. He said that the existence of these programmes means that certain common calculations can be carried out with scarcely any effort beyond that of feeding the initial data into the computer. On the Manchester machine it has been found that the speed factor over hand computation is often of the order of 150 : 1—an ample repayment for initial time spent on programming.

Mr. Livesley defined the ideal programme as one which carries out all the calculations of a problem, from the data on the designer's drawing-board to the final facts he wants to know, and which is sufficiently flexible to cover all problems of a given type. The first requirement helps to cut down possibility of error, while the second avoids the necessity of developing new programmes for very similar work. One usually finds that the human beings preparing data for a machine are far more prone to error than the machine itself, and consequently it is essential to make the input of data as simple as possible, getting the machine to do the easy parts of the calculation as well as the most difficult. The advent of computers, and the demand for flexibility in programmes, has led to interesting developments in numerical analysis. New methods, especially suited to automatic machines, have shown definite superiority when compared with methods generally in use on desk calculating machines.

At the present time, continued Mr. Livesley, there is a lack of programmes and programmers rather than of computing machines. It is only as programmes are developed for standard calculations that the existing machines can be fully used. The training time for a programmer is from three to twelve weeks, with a similar period for the time usually required to develop a programme for a given calculation. Mr. Livesley concluded by emphasizing that the efficient use of a computing machine depends entirely on the programmer.

The subject of Mr. Alway's paper was the application of the ACE, the machine at the National Physical Laboratory, Teddington, to aircraft design problems. Supplementing some remarks of Prof. Williams, Mr. Alway said that the ACE group also instructs people in the use of their machine, and, in addition, a large team of programmers enables them to undertake work directly. The pilot model of the ACE has been in operation for eighteen months, and during this time a considerable library of programmes has been built up. The machine has only a limited high-speed store; but the use of Hollerith punched cards as an auxiliary store has been very successful. Certain features of the logical design of the machine enable calculations to be done while cards are being read or punched. By this means the disparity between the speeds of operation of the auxiliary store and the working store is largely overcome.

The pilot model has been very successful in dealing with problems of matrix arithmetic. Programmes for solving sets of linear simultaneous equations have been made using the card store already described.

These can solve sets involving up to 192 unknowns and can invert matrices of orders up to 95. Programmes have also been made for finding the latent roots and vectors of matrices. A fast programme, in which all the numbers concerned are kept in the high-speed store, can deal with symmetric matrices of order 19 and unsymmetric matrices of order 15. For matrices of higher orders, punched cards are used as an auxiliary store. Similar programmes exist for dealing with complex latent roots. All these programmes are in constant use, and many applications have been made to problems arising in aircraft design.

Mr. Alway then described a typical problem of aerodynamic design, namely, the flutter problem. Flutter is the condition where the aerodynamic forces tend to reinforce the elastic forces in a vibrating wing, and the aeroplane must be designed so that this will not occur at any speed at which it is supposed to fly. The differential equations representing the complete motion of the whole aircraft as an elastic body subject to aerodynamic forces are intractable, but design engineers are helped if, as a first approximation, the modes of vibration of the aeroplane *in vacuo* are obtained. This involves finding the latent roots and vectors of a matrix. For the complete flutter problem the equations can be set up for a limited number of degrees of freedom, and their solution amounts to finding values of velocity and frequency which make a certain determinant zero. Each element of this determinant is of the form $a\omega^2 + ib\omega + c + e/V^2 + id$, where ω is the frequency, V the aircraft velocity, and a, b and c to some extent depend on ω. One programme for dealing with this part of the flutter problem is arranged so that the complex determinant is evaluated for pairs of values of ω and V, and the values of ω and V which make the determinant zero are then found by interpolation. The computation time for a single determinant of order 8, corresponding to 8 degrees of freedom, is a quarter of a minute.

In conclusion, Mr. Alway pointed out that, unlike analogue simulators, an automatic digital computer becomes more powerful as more programmes are developed and existing techniques stream-lined.

THE PHARMACIST AND THERAPEUTICS

THE British Pharmaceutical Conference, held during August 31–September 4, looked back through ninety years to its foundation in 1863, and its chairman this year, Dr. G. R. Boyes, contributed to it a valuable address entitled "The Pharmacist and Therapeutics". Three years before the long series of these conferences began, Oliver Wendell Holmes stated his belief that, if the whole of the materia medica then in use in the United States could have been sunk to the bottom of the sea, it would have been "all the better for mankind and all the worse for the fishes"; and Dr. Boyes considers that these words could have been applied also to the British materia medica of that day. The publication of the first British Pharmacopœia was a major step towards the improvement of British pharmacy, and the records of successive British Pharmaceutical Conferences show how much the pharmacists have contributed to the subsequent improvement in the methods of preparation, formulation and analytical control of substances used for the treatment and control of disease. Dr. Boyes, in his address, reviewed some of the many important contributions made by pharmacy to the materia medica of to-day.

The primary functions of a pharmacist are to provide the drugs and preparations of drugs needed by medical men, to see that these are pure and active and that they are supplied in forms suitable for the various methods of administration of them. The pharmacist thus bears a great responsibility and must have a thorough knowledge of the chemistry and physics of drugs, of analytical methods used for their assay and of the principles of drug formulation. He needs also a knowledge of physiology and pharmacology. The 'chemist', in other words, from whom we buy our pills and potions is highly skilled in his job and is carefully trained for it. He has, however, fewer opportunities nowadays to exercise his skill in the art of compounding medicines, and more and more is he asked to supply medicaments which reach him ready for use.

Outstanding features of modern pharmacy are the extensive use of synthetic substances and the decline in the use of crude preparations, for which isolated substances active in them have been substituted. Synthetic substances were introduced as long ago as 1896; but their use has greatly increased during the past ten or twenty years, and Dr. Boyes quoted figures which indicate the astonishing growth and magnitude of the industry now engaged in the manufacture of these synthetic substances and isolated active principles. He rightly emphasized the value of the contributions made by pharmacy to this remarkable development.

The discovery of a new drug, whether it is used by medical men or veterinarians, is seldom due to chance. It is usually the result of long periods of co-ordinated research, the testing of scores or hundreds of synthetic compounds, and the choice, as a result of all this work, of a few substances which promise to give the required balance between efficacy, ease of administration and a minimum of cost and of toxicity to the patient. The public are seldom fully aware of the amount of work of this kind involved, or of the degree of skill, experience and training needed for it. As Dr. Boyes says, work of this kind has developed for us a variety of drugs in use to-day, among which are the derivatives of barbituric acid, synthetic œstrogens and other sex hormones, sulphonamides, antimalarial drugs and drugs which reduce pain or induce anæsthesia.

At the same time, drugs derived from plants and animals have not been neglected. Dr. Boyes tells us of the work done on some of these. Among the plant-products are khellin, quinine, digitalis and morphine. The laboratory synthesis of morphine has recently been accomplished—a feat which only the chemist can rightly assess. Other plant-products are penicillin, streptomycin, aureomycin and the other antibiotics, to which new ones are constantly being added. Among animal products are the various hormones, the substances used for blood-transfusions and antitoxins. Dr. Boyes gave special attention to the work on corticotrophin, insulin and the recent isolation by chromatographic methods from raw liver of cyanocobalamin, which is also produced by *Streptomyces griseus*, the organism which yields streptomycin.

The remainder of Dr. Boyes's address was devoted to sections on the analytical control of drugs and to their biological and clinical trials. This part of the address showed clearly that, when a therapeutic substance has been discovered or synthesized, a great deal more remains to be done before it can be released for use. It is necessary to make sure that its pharmacological and therapeutic activities do not vary from batch to batch of the manufactured product. The biological activity of drugs which cannot, for various reasons, be made in a chemically pure state must be controlled by biological tests on animals; and carefully planned and rigidly controlled clinical trials on human patients are done whenever these are possible. Nor must we forget the considerable work required to ensure that the drug is issued in a form in which it shows its characteristic properties, that it is safe and convenient to use and that it remains stable for a reasonable time under the climatic conditions to which it is to be subjected. This task, known as the formulation of medical substances, is the responsibility of the pharmacist.

Discussing the international aspects of drug-production, Dr. Boyes commented on the growing need for close international collaboration between the pharmacists of all nations and indicated the progress made in this respect. The publication by the World Health Organization of an International Pharmacopœia should help to extend international agreement on standards for drugs and pharmaceutical preparations.

In conclusion, Dr. Boyes discussed the responsibilities of the pharmacist and claimed that modern pharmacy should be, not the handmaid of medicine, but its co-partner with equal responsibilities. His address will evoke much sympathy with this view. Some readers of it will wonder, however, why it does not consider the needs and work of the modern veterinarian, who is, to an ever-increasing degree, collaborating with, and making important contributions to, human medicine. A future which gave us the medical man, the veterinary surgeon and the pharmacist as equal partners in a humanitarian team would indeed be worth living to see. There is much evidence that it will, in fact, be the heritage of a generation not very far removed from the one to which Dr. Boyes belongs. G. Lapage

A NEW FOSSIL MAN FROM SOUTH AFRICA

By Dr. J. C. TREVOR

Department of Archæology and Anthropology, University of Cambridge

In January 1953, Mr. Keith Jolly, an archæologist, recovered the major portion of a human calotte from the surface of a wind-eroded site about midway between the village of Hopefield in the Cape Province and the southernmost extension of Saldanha Bay. Only brief preliminary accounts of the Hopefield site and 'Saldanha Man' by A. J. H. Goodwin (*S. Afric. Archæol. Bull.*, No. 30, 41, Claremont, Cape Town; 5*s.*) and Prof. M. R. Drennan (*S. Afric. J. Sci.*, 50, 7 (1953); *Illust. Lond. News*, No. 5971, 480 (Sept. 26, 1953), 2*s.*) have so far appeared, and even since these were written additional information relating to the discovery has become available. Curiously enough, C. P. Thunberg (1743–1828), who was to succeed Linnæus at Uppsala in 1784, had in his thirtieth year visited the farm Elandsfontein, on which most of the site lies, and he later described its flora and fauna. The fossiliferous nature of the Elandsfontein deposits, however, did not become apparent until shortly after the Second World War, and credit for ensuring that their possibilities were not neglected must be given to a small committee formed under the chairmanship of Prof. Drennan at the University of Cape Town.

A rare giraffid (*Griquatherium*) occurs among the fossil mammals, of which the extinct forms are represented most abundantly by the Cape horse and the living forms by several genera of the commoner African antelopes. The fluorine content of the remains of a selected series of the extinct animals, including the giant wart-hog *Mesochoerus*, and that of the human skull-vault, were recently determined in London by C. F. M. Fryd, of the Government Chemist's Department, and there is a remarkable agreement between them. Because of the high rate of fluorination at the site, Dr. K. P. Oakley, of the British Museum (Natural History), who recently inspected it, considers that their geological ages are, within narrow limits, identical. On the basis of faunal and archæological correlations elsewhere in the Union, he also tentatively supposes that the man of Hopefield should be associated with the Late Acheulean or Fauresmith hand-axes, characteristic of the South African Earlier Stone Age, rather than with the Still Bay points, which typify the Middle Stone Age. Artefacts belonging to both cultures are found on the site; but those of the Still Bay indicate only its earlier or typical phases. No trace of the use of fire has yet been observed.

The human bones, which are being studied by Prof. Drennan, comprise the frontal, both parietals, and the occipital of a young adult subject whose probable sex is regarded as male. Their owner was manifestly different from any normal member of the species *Homo sapiens*, and what is preserved of him bears a strong resemblance to the cranium from the Broken Hill Mine in Northern Rhodesia, accidentally brought to light on June 17, 1921, and now at South Kensington. The most detailed examination of the Rhodesian skull is that made by Dr. G. M. Morant (*Ann. Eugen.*, 3, 337; 1928), who concluded that, although more closely related to certain Neandertaloid types than to modern man, it could be clearly distinguished from both. A striking feature shared by the Hopefield and Broken Hill specimens is the lateral massiveness of the torus, or bony bar, above the orbits—not so pronounced in the Hopefield calotte, of which almost the entire missing left brow-ridge has lately been retrieved—but Prof. Drennan is also impressed with the apparent affinities of the new African find to the far-removed ancient Ngandong hominids of central Java. The results of his investigation will be eagerly awaited in view of the importance they are bound to have for the advancement of knowledge in the field of human palæontology.

OBITUARIES

Sir Thomas Taylor, C.B.E.

The sudden death on August 29 of Sir Thomas Taylor will be mourned by members of universities and allied bodies throughout the world. Widely known, loved and respected, his untimely death at the age of fifty-eight will come as a cruel blow.

Fellow and former Scholar of Brasenose College and a Rhodes Travelling Fellow, he taught and made distinguished contributions to chemistry, notably stereochemistry. His name is connected with two standard works, the English revision of "Richter", the second volume of which he edited, and Sidgwick's "Organic Chemistry of Nitrogen", which he revised in conjunction with Prof. Wilson Baker.

He served with distinction in the two World Wars, and in the second played a major part in the organization of the British Commonwealth Scientific Office in Washington, as well as serving as scientific adviser to the Supreme Allied Commander, South-East Asia. Afterwards, he became principal of the University College of the West Indies, in Jamaica, and in 1952, of the University College of the South-West, Exeter. It is fitting that his services were recognized by the award of the C.B.E., and later, of a knighthood.

A mere catalogue of Sir Thomas Taylor's distinguished career and singular range of achievements, however, would form an inadequate tribute, for he was a man of many parts, an impressive scholar, gifted with an acute and agile mind, which, coupled with vision and prodigious energy, marked him as an outstanding university administrator. He was a man of paradoxes as well as of parts. A vivid personality, yet modest; disconcertingly direct, yet kind; a man with clear-cut likes and dislikes, yet deploring alike fulsome praise and harsh criticism. He was a scholar with a zest for living and had a rich human understanding, with a pervasive sense of humour. Cultured, widely travelled, with a rich store of anecdote, aided by a remarkable memory, to receive his hospitality, and to listen to his witty, well-informed conversation, was an engaging and stimulating experience.

Of his many achievements, both in his beloved Oxford and elsewhere, none can be judged greater than his leading part in the creation of the University College of the West Indies, in the form envisaged in the Irvine Report. His discharge of the duties of first principal was masterly, and won for him universal respect and admiration. All who served with him have reason to remember his wisdom, guidance and example with enduring gratitude. He faced unflinchingly the unending succession of stern tasks inevitable in the creation of a new institution of this character, and owing to his unfailing wisdom, leadership and immense drive, they were accomplished. When, in 1951, all seemed to have gone so well, the young and growing college was seared by a devastating hurricane at a most critical time. It was his courage, determination and buoyancy of spirit that did so much to allay discouragement and to re-invigorate all efforts. Despite the pressure and burden of administration, he spared no pains to come to know every member of his staff and all undergraduates, and his sympathetic guidance was always freely given.

The universities and colleges Sir William served were not alone in receiving the benefits of his scholarly gifts and administrative experience, for they were given unstintingly in the wider sphere of higher education within the British Commonwealth, and societies fostering cultural activities in many forms received his valued support, together with that of Lady Taylor. Musicians, naturalists and bird lovers with unbounded enthusiasm, their combined activities have enriched the annals of such organizations in many parts of the world.

His passing will be deeply felt by friends scattered throughout the world. To Lady Taylor, who survives him, we offer our deepest sympathy.

Norman Millott

Prof. E. C. Jeffrey

Edward Charles Jeffrey, professor of plant morphology at Harvard University, died on April 19, 1952, in his eighty-sixth year. A Canadian by birth, and a graduate of the University of Toronto, he received a doctorate from Harvard University in 1898, and in 1902 was made a member of its Faculty. His position in the field of botanical research is attested by a list of 115 publications, and his success as a teacher is evidenced by some thirty graduate students trained under his direction and well represented among active American botanists.

Prof. Jeffrey was one of that small band of British post-Darwinian plant morphologists including Scott, Bower, Worsdell and Gwynn-Vaughan which, at the beginning of the century, set itself to reconstruct the evolutionary history of vascular plants. At the very outset of his studies, Jeffrey took up the stelar theory of van Tieghem and established it on a sound foundation. Then he began a search for valid evolutionary criteria applicable to the vegetative parts of vascular plants. He utilized the current biological doctrines of retention, reversion and recapitulation in an attempt to relegate them to their proper phyletic positions and, above all, he explored the fossil record, which he realized was the final court of appeal in evolutionary problems. He was a pioneer in the work on Mesozoic lignites and, incidentally, he brought the celloidin technique to a point of high precision. From the lignites it was but a step to the study of the microscopy of coal, a subject to which he devoted enormous labour. He advanced a sound anatomical interpretation and ecological explanation for the evolution of angiosperm herbs from woody ancestors. In his later years, he turned to cytogenetics and was a pioneer in the assertion that "the angiosperms are a mass of hybrids", and that an evolutionary theory based upon the cavortings of *Oenothera lamarckiana* was indeed a "mutation myth".

Prof. Jeffrey was a creative genius and a man of strong enthusiasms and convictions. Almost of necessity he became a controversial figure in American botany. He was a Darwinian who lived to see the superb confidence of his predecessors called in question, and their positive ideals supplanted by a mechanistic and negative outlook. Many of his conclusions ran counter to long-established views, and he met the common fate of the iconoclast. The criticisms levelled against him were often unfair and were based upon superficial understanding and wounded vanity. A policy of studied neglect was effectively applied to his work and others reaped where he had sown.

But the tide is turning, and some leading American workers are already aware of the fact that later discoveries have supported Jeffrey's views surprisingly. It is a safe prediction that the future will set his name high on the roll of those who have made permanent contributions to the philosophy of botany. Then the words of his own sturdy faith, so often repeated, will be amply justified: "Good work tells in the end".

Ray E. Torrey

NEWS and VIEWS

Research at the Wellcome Foundation: Dr. J. W. Trevan, F.R.S.

On August 31, Dr. J. W. Trevan retired from his appointments as director of the Wellcome Research Laboratories, Beckenham, and temporary director of research in the Wellcome Foundation, Ltd., the latter post dating from the death of the late Dr. C. H. Kellaway. Dr. Trevan obtained his medical qualification in 1911, and thereafter for some years worked in the Physiology Department of St. Bartholomew's Hospital, London, where he studied renal secretion, respiration, ketosis in diabetes, and the viscosity of the blood. In the First World War he served as pathologist in the Royal Army Medical Corps in the Near East, and returned to England in 1920 to join the staff of the Wellcome Physiological Research Laboratories as pharmacologist. Here his studies covered a wide diversity of subjects, such as local anæsthetics, the chemotherapy of trypanosomiasis, and quinine alkaloids. He became interested in the biological assay of insulin, and soon was keenly aware of the fallacies inherent in the methods then used for this purpose. Being of a mathematical turn of mind, he applied himself to a statistical study of the subject and ultimately evolved the '*LD*50' technique which is now widely used in assessing toxicity. This work was published in the *Proceedings of the Royal Society*, of which Society he was elected a Fellow in 1946. Latterly, his energies have been devoted mainly to administration, and it was under his direction that vast quantities of biological products used by the medical services during the Second World War were prepared. Although now retiring from his administrative appointments, Dr. Trevan, in the capacity of special consultant, is maintaining his connexion with the Wellcome Foundation.

Dr. D. W. Adamson

Dr. D. W. Adamson, who succeeds Dr. Trevan as research director of the Wellcome Foundation, Ltd., and director of the Wellcome Research Laboratories, Beckenham, graduated at Manchester in 1932, proceeded to a Ph.D. under Prof. J. Kenner, and was a demonstrator until 1936. He then went to Magdalen College, Oxford, worked under Sir Robert Robinson for three years and graduated D.Phil. He spent the war years at the Chemical Defence Experimental Station, Porton, becoming the head of a section dealing with the identification of war gases. Towards the end of the War he went to Germany with a temporary commission to work with the Allied scientific intelligence organization. He joined the Wellcome Chemical Research Laboratories in 1945 and, on the retirement of Dr. Sydney Smith and the reorganization of the Wellcome Research Laboratories in 1948, he became head of the Chemical Division under Dr. Trevan, then director of the Beckenham laboratories. Dr. Adamson's own particular interest at the Wellcome laboratories has been centred largely around compounds of the propanolamine and allylamine types. The intensive and extensive chemical work he has carried on over the years has given an extraordinarily fruitful harvest of compounds of pharmacological interest and therapeutic value. Among these are a potent antihistamine, an analgesic for dogs (a species intolerant to morphine), and some spasmolytics used in the treatment of Parkinson's disease and for the inhibition of gastric motility. All this work, in which, of course, Dr. Adamson collaborated with several colleagues, both pharmacological and chemical, has demonstrated his ability to lead teams of workers; his new appointment gives him much wider scope for the organization of research, for which he has shown great aptitude.

University College in Southern Rhodesia

At the invitation of the Inter-University Council for Higher Education in the Colonies, a delegation from the Rhodesias and Nyasaland recently visited London to discuss the plans for a university college in Central Africa (see *Nature*, July 4, p. 1). The delegation was largely representative of the Rhodesian University Inaugural Board, and during its visit it had discussions with the Inter-University Council and with representatives of the University of London. Full agreement in principle was reached regarding the establishment of the university college, and it was also proposed that it should seek to enter into a special relationship with the University of London. After these discussions, the Government has provisionally agreed to make a grant of £1,250,000 from the Colonial Development and Welfare Fund towards the establishment of a university college open to all races at Salisbury, Southern Rhodesia. The grant is subject to certain conditions, regarding particularly the adequacy of the site, the autonomy of the administering body and to provision being made for recurrent expenditure to be met from other sources. Fuller details will be announced when the delegation has returned to Salisbury and has discussed these proposals with the inaugural board and the authorities concerned in Central Africa.

United Kingdom Agricultural Representatives in the United States

The following announcements have been made by the Agricultural Departments of the United Kingdom: Mr. B. A. Cash-Reed, food attaché in Washington, has been appointed attaché for food and agriculture; Mr. Neil Frank McCann has taken up his duties as agricultural adviser (technical) in the United States, and is attached to the United Kingdom Scientific Mission in Washington; Mr. M. Whalley Taylor, deputy agricultural attaché, has returned to the United Kingdom.

Mr. N. F. McCann was a student at the Harper Adams Agricultural College and in 1929 he obtained the B.Sc. degree in agriculture of the University of London. After practical farming experience, he joined the staff of the Cheshire School of Agriculture. In 1939 he was seconded to the Cheshire War Agricultural Executive Committee. Since 1946 he has been county agricultural officer in Nottingham.

Nuffield Gerontological Research Fellowships

The Nuffield Foundation invited applications some time ago for a Nuffield Research Fellowship for research on the scientific aspects of ageing, to be awarded by a selection committee appointed equally by the Royal Society of London and the Foundation. One fellowship of professorial status or alternatively one or more of less senior status was proposed. The Foundation was, however, impressed by the quality of the candidates, and decided to award two fellowships, one of professorial and one of less senior status; in order to meet the additional award the sum which was reserved has been increased from £25,000 to

£51,000 and the following awards have been made. *Nuffield Professorial Research Fellowship in Gerontology:* Dr. P. L. Krohn, reader in endocrinology, University of Birmingham. Dr. Krohn has taken up his appointment, and his programme of research, aimed at "a causal analysis of the process of ageing", includes a study of the interactions of tissues and their environments (chiefly by grafting tissues of animals of one age into animals of another age), and a study of the factors controlling the duration of reproductive life in primates. This appointment is for five years in the first place and is renewable. *Nuffield Gerontological Research Fellowship:* Dr. D. A. Hall, lecturer in medical biochemistry, University of Leeds. Dr. Hall will take up his fellowship on January 1, 1954. He proposes to study the changes in connective tissue associated with ageing. This appointment is for three years in the first instance.

Vacation Course in Synoptic Meteorology

Since 1950, when the pioneer course was held, the Royal Meteorological Society, in conjunction with the Council for the Promotion of Field Studies, has held a vacation course in elementary synoptic meteorology yearly at the Council's field-centre at Malham Tarn. The fourth such course took place this year during September 9–16 and was attended by some thirty students. There was the usual wide cross-section of ages and occupations. The instructors were Mr. James Paton (director of the course), Scottish secretary of the Royal Meteorological Society and senior lecturer in meteorological physics at the University of Edinburgh, and Mr. C. D. Ovey, a vice-president of the Royal Meteorological Society and lecturer in geography in the University of Cambridge. Visiting lecturers included Mr. F. E. Lumb, senior meteorological officer at the the Air Traffic Control Centre, Preston, who spoke on the organization of a meteorological station; Prof. R. F. Peel, of the Geography Department, University of Leeds, who gave a talk on the work of the Ruwenzori Expedition, Central Africa; Mr. N. Pye, lecturer in geography in the University of Manchester, who showed a film taken on a recent visit to the arid zone of Arizona; and Mr. R. G. Veryard, secretary of the Royal Meteorological Society and assistant director of the Meteorological Office at Harrow, who gave a lecture on certain aspects of climatology. Practical aspects of the course consisted of observation work; the Malham Tarn Field Centre is well equipped for this purpose, many of the necessary instruments having recently been provided, on permanent loan to the Centre, through the generosity of various instrument manufacturers. Various education authorities and the Education Department of the R.A.F. made it possible for some of the students to attend the course, which is approved for grants in suitable cases. A similar course will be held in late August 1954—a little earlier than this year so that more members of school teaching staffs and sixth-form students will be able to attend before the autumn term begins.

"Flying Saucers"

In an article in *Science* (118; 1953), C. C. Wylie, of the State University of Iowa, describes his investigations into the 'flying saucers' which have been much observed in the United States. Wylie concludes that these are simply reflected sunlight, having the following characteristics: (1) they are seen only when the sun is shining; (2) they are generally seen in the part of the sky opposite the sun; (3) there is only one sighting on each saucer, as the area for the critical angle is small.

Oil Pollution of the Sea

An international meeting of private citizens representing ten nations is to be held in London on October 27 next to press for action on the evil caused by oil pollution of the sea. The meeting will be held in the lecture hall of the Institution of Electrical Engineers, Savoy Place, London, W.C.2, from 11 a.m. to 4.30 p.m. The conference has been convened by the independent committee which has been working for the past two years to arouse public opinion on the need for action on the subject. The committee's task has been greatly assisted by the publication of an official report made to the Minister of Transport during the summer, which reached the conclusion that the only effective way of solving the problem was to prohibit ships from discharging waste oil into the sea. To achieve this, international agreement would be necessary. The purpose of the conference is to bring the findings of the report before public opinion in all countries. The chairman of the meeting will be Mr. James Callaghan, M.P., and the Minister of Transport will open the conference. Other speakers will include Mr. D. F. Anderson (chairman of the General Council of British Shipping), Lord Hurcomb, Sir Douglas Ritchie (chairman of the executive committee, Dock and Harbour Authorities' Association), Mr. Mogens Black (director of the Port of Copenhagen), M. Leon Lippens (mayor of Knokke, Belgium), Mr. Banks Belt (chairman of the Atlantic Waterfowl Council, New York) and Prof. J. Berlioz (Natural History Museum, Paris). A number of local authorities are sending representatives, and the Minister of Housing and Local Government has stated he will be prepared to sanction, on application, the expenses of one delegate to attend the conference from local authorities whose boundaries form part of the coastline. Admission will be by ticket only, which can be obtained by sending a stamped, addressed envelope to Miss P. Barclay-Smith, Secretary, Co-ordinating Advisory Committee on Oil Pollution of the Sea, I.C.B.P. (British Section), c/o British Museum (Natural History), Cromwell Road, London, S.W.7.

Modern Science and Christian Thought

A course of ten lecture-discussions designed to explore the contemporary form of the relation between science and religion is being held at St. Anne's House, Soho (57 Dean Street, London, W.1), on successive Thursdays until December 17 (October 22 excepted) at 6.30 p.m. The first lecture—on the history of the debate between science and religion—was given on October 8, and the future meetings will consider the following topics: creation and the expanding universe (Prof. C. A. Coulson); the scientific approach to historical study and Christian presuppositions about history (Miss C. V. Wedgwood); body, brain, mind and spirit—modern physiology in relation to the incarnational view of man; the scientific approach to psychology and Christian presuppositions about human nature—a dialogue between a psychologist and a Christian philosopher; the scientific approach to social science and Christian presuppositions about human relations—a dialogue between Prof. H. B. Acton and Prof. Michael Fogarty; man and evolution—modern biological science in relation to Christian ideas of man's place in Nature (Dr. David Lack); scientific objectivity in relation to faith—a dialogue between Mr. H. J. Blackham and Mr. Michael Foster; space, time and matter—the world-view of modern physics (Dr. G. J. Whitrow); theology and the future of science—a general symposium. The method to be adopted at each meeting will be to survey the most modern findings and feelings of each of the relevant fields of science and see what relation they have to Christian presuppositions about the subject-matter of those sciences; the attempt will be made to discover where points of tension occur and whether this tension in different cases is due to the need for re-formulating certain Christian beliefs, revaluation of scientific theories or simply to an illegitimate claim on either side that its particular type of language is exclusively valid. The admission fee for each lecture is 1*s*. 6*d*. for members of St. Anne's House and 2*s*. for non-members.

X-Ray Analysis Group of the Institute of Physics: Autumnal Conference

THE X-Ray-Analysis Group of the Institute of Physics will be holding its annual autumn conference and exhibition during November 20–21 at the Institution of Electrical Engineers, Savoy Place, London, W.C.2. The conference will be divided into four sessions as follows: film methods and microdensitometry; counter spectrometry; the objects of the Equipment Sub-Committee; and identification by X-ray analysis. In addition, there will be an evening discourse on November 20 by Dr. R. W. G. Wyckoff, who will give a survey of X-ray diffraction in the United States. The exhibition will be on X-ray crystallographic equipment and will be divided into a commercial and a research section. The conference and exhibition are open to all, without charge, on completion of an application form, copies of which can be obtained from the Deputy Secretary, Institute of Physics, 47 Belgrave Square, London, S.W.1. The secretary of the conference is H. J. Goldschmidt, B.S.A. Group Research Centre, Greystones Hall, Greystones Hall Road, Sheffield 11.

Harwell Isotope School

INTEREST in the continually growing use of radioactive isotopes throughout the world and the demand from universities, hospitals and industrial organizations abroad are now at the rate of four thousand consignments for instruction, and this has compelled the Isotope School of the Atomic Energy Research Establishment, Harwell, to introduce an additional course for the second time this year. The School was started two years ago to teach the techniques of using and handling radioactive materials to scientists, doctors and industrial research workers. The series of courses planned for this year did not include one for July, but one had to be arranged and was filled. There is still such a heavy demand for places that another extra course will be held during November 16–December 11. Applications to be considered for this course should be sent to the Isotope School, Atomic Energy Research Establishment, Harwell, Berkshire. More than two hundred and fifty students have so far attended the school, from twenty different countries. Isotopes are now being sent out from Harwell at the rate of 11,000 a year, of which four thousand are exported. The fee is £40 for the course, and accommodation may be arranged for students at an additional charge of £7 7*s*. a week.

Chemistry and Physics of Synthetic Fibres

THE Plastics and Polymer Group of the Society of Chemical Industry is arranging a symposium on "The Chemistry and Physics of Synthetic Fibres", to be held in the lecture theatre of the Institution of Electrical Engineers, Savoy Place, London, W.C.2, during March 24–26. Papers will be presented and discussed on the chemical and physical basis of fibre formation and the properties of fibres in relation to the molecular structure and conditions of formation, the phrase 'synthetic fibres' being interpreted in the broader sense, meaning material brought into a fibrous structure by a manufacturing process, irrespective of the source of the raw materials. In order to limit the scope of the symposium, the process of dyeing, the properties of textiles, the economics of the industry and historical surveys will not be included as major items, although reference may be made to such topics if they have an important bearing on the basic theme of the symposium. Papers will be presented in full, but will not usually take more than 30–40 minutes each. Preprints will be available, and authors should submit their manuscripts before November 1. Those with insufficient material for a full paper will be able to present their ideas in the discussions. All communications relating to the symposium should be addressed to Mr. A. R. Burgess, Plastics and Polymer Group, Society of Chemical Industry, 56 Victoria Street, London, S.W.1.

Announcements

DR. A. A. WELLS has been appointed chief research engineer and head of the Engineering Research Station, Abington (nr. Cambridge), of the British Welding Research Association; in addition, Mr. R. P. Newman has been appointed chief administrative officer of the Station.

THE Institute of Metal Finishing has awarded its Westinghouse Brake and Signal Co., Ltd. Prize for 1952–53 to Dr. A. E. Davies, Mr. R. M. Angles and Dr. J. W. Cuthbertson, joint authors of a paper on the complex fluorides for the deposition of tin and tin alloys.

THE annual conference of the British Institute of Management will be held at Harrogate during November 11–14. Further information can be obtained from the Director, British Institute of Management, Management House, 8 Hill Street, London, W.1.

THE American Society for the Study of Sterility is offering a prize of a thousand dollars for an essay on the subject of infertility and sterility. Essays must be submitted not later than March 1, 1954. Further details concerning the competition can be obtained from the secretary of the Society, Dr. Herbert H. Thomas, 920 South 19th Street, Birmingham, Alabama.

THE Royal Institute of Philosophy has recently announced its lecture programme for the session 1953–54. The session opens with a course of six lectures on "Fundamental Questions of Philosophy" by Dr. A. C. Ewing. All lectures are given on Fridays at 5.30 p.m. at University Hall, 14 Gordon Square, London, W.C.1, the first one being on October 16. The lectures are open to the public, and programmes for admission can be obtained free of charge upon enclosing a stamped addressed envelope to the director of studies, S. E. Hooper, at the above address.

SCIENTIFIC CIVIL SERVICE

PROMOTION OF INDIVIDUAL RESEARCH WORKERS

SPECIAL posts have again been created this year in the Scientific Civil Service under provisions included in the White Paper (Cmd. 6679; 1945) designed to provide for the promotion of individual research workers of exceptional merit. The promotions are effective from July 1.

Deputy Chief Scientific Officers

DR. S. G. BAUER has worked in the British Atomic Energy project since its earliest war-time days. He was a member of the British team in Canada, and returned to Great Britain when the Harwell establishment was opened. His work has been mainly devoted to the development of nuclear power reactors, and he has made great advances in the technology of the special materials and processes which such reactors require.

DR. S. J. FOLLEY, who since 1945 has been head of the Physiology Department of the National Institute for Research in Dairying, Reading, joined the staff of the Institute in 1932 and has since then been working on various physiological aspects of lactation and reproduction. Much of his research has been on the endocrinology of these related activities, on mammary growth and on the biosynthesis of milk fat, and he has made substantial contributions to knowledge in each of these three fields. He was a Rockefeller Foundation Fellow in 1938, studying at Yale University. He is at present chairman of the Society for Endocrinology. He was elected a Fellow of the Royal Society in 1951.

DR. P. FORTESCUE worked before and during the Second World War with the Bristol Aeroplane Co., Ltd., on gas turbine development, making notable advances in axial and centrifugal compressors and in automatic control systems. At the Atomic Energy Research Establishment, Harwell, he is in charge of the Engineering Laboratory, working primarily on heat-transfer problems connected with nuclear reactors, and on the development of special pumps and compressors.

DR. G. G. MACFARLANE joined the Telecommunications Research Establishment of the Ministry of Supply in 1939 after carrying out research on theoretical problems in electrical engineering at the Technische Hochschule, Dresden, as Matthew Gray Scholar of the University of Glasgow. He has done important fundamental work in quantum mechanics and electromagnetic theory. He has also been prominent in the investigation of theoretical problems arising in the development of radar equipment and has made valuable contributions in this field.

Senior Principal Scientific Officers

MR. G. E. BACON joined the Atomic Energy Research Establishment, Harwell, in 1946, after war-time service in the Telecommunications Research Establishment on the development of ground radar equipment, particularly aerial systems. At Harwell he has worked on the application of X-ray and neutron diffraction techniques to the study of the solid state. An important part of this work has been research on the structure of graphite and investigations of single-crystal methods of neutron diffraction analysis.

DR. E. H. BATEMAN's varied experience included structural engineering, educational work in the R.A.F. and lecturing in civil engineering at the University of Birmingham before he joined the Ministry of Home Security in 1939 to work on camouflage. In 1944 he transferred to the Armament Design Establishment, Ministry of Supply, and in 1952 to the Royal Aircraft Establishment. While at the former Establishment he not only carried out much valuable design work but also made special investigations into the analysis of mechanisms. In addition, he produced his well-known second-order iterative solution for solving algebraic and transcendental equations and for the inverse interpolation of functions, together with his development of matrix solutions for vibration problems involving structural discontinuities and for statistical problems which are beyond the practicable range of existing methods. At the Royal Aircraft Establishment he has done valuable work on thermal stresses caused by kinetic heating of high-speed aircraft and guided weapons.

MR. J. B. BRATT joined the National Physical Laboratory, Teddington, in 1937, where he has carried out valuable work in the measurement of aerodynamic forces on oscillating aerofoils for both subsonic and supersonic flow. His applications of electrical methods to the technique of measurement are outstanding. They have been of very great value both in providing experimental checks on results given by theory, and in exploring difficult problems where theory is uncertain—for example, those concerned with nearly or completely stalled flow, effects of Reynolds number, influence of compressibility especially in the transonic region, and effects of aerofoil thickness. The information obtained from such work is vital for the prediction of the behaviour of modern high-speed aircraft.

MR. R. DONALDSON joined the National Physical Laboratory, Teddington, in 1928 after two years as demonstrator in the Physics Department of the University of Edinburgh. He has been primarily occupied with the theoretical development of the quantitative evaluation of light, covering the whole field of colorimetry, heterochromatic photometry and spectrophotometry, and has made notable contributions to all these branches of the subject by the design of instruments and the development of techniques to meet the ever-widening requirements of industry. His name first became prominent in this field with the development of his trichromatic colorimeter, which he described in 1935 and which is now the most widely used trichromatic colorimeter in the English-speaking countries. His most recent work is concerned with the re-determination of the constants of the C.I.E. system of colour measurement and with problems of fluorescence.

Dr. S. Neumark had considerable experience before the Second World War as a lecturer and research worker in aerodynamics and applied mathematics in Warsaw, at the Technical University, the Aerodynamic Institute, and the Institute of Aeronautical Research. During 1937–39 he was professor of mechanics in the Polish Air Force College, Warsaw, and while in the Polish Air Force he joined the Royal Aircraft Establishment, Ministry of Supply, remaining there on demobilization. He has done distinguished work in theoretical aerodynamics, especially investigations into problems of stability and control and in fluid motion, including theoretical flow over swept-back wings, and he is widely known for his researches in these fields.

Dr. W. G. S. Parker entered the Royal Aircraft Establishment, Ministry of Supply, in 1936. He worked initially on a wide variety of physico-chemical problems in the aircraft field and made many valuable contributions. Since 1946 he has been concerned with the difficult problems of the mechanism of burning and decomposition of oxidizing fuels and propellants, and his work in this sphere has earned him an international reputation. In particular his research on carbon formation and on the structure of diffusion flames has advanced considerably the understanding of combustion in air flames and has had important applications in the study of fire prevention.

Dr. S. M. Partridge, for two years prior to joining the D.S.I.R., held a Beit Memorial Fellowship for Medical Research, working at the Lister Institute for Preventive Medicine. He joined the D.S.I.R. in 1942 to assist a team at the Low Temperature Research Station, Cambridge, studying dehydrated meat, and was responsible for the development on the pilot-plant scale of a process for its manufacture. Since the Second World War, in the course of his investigations on connective tissues (cartilage, elastic tissues, etc.), he has made notable contributions to analytical methods in biochemistry. He was a pioneer in the application of partition chromatography on filter paper to the analysis of sugars and in the development of displacement chromatography of organic compounds using ion-exchange resins. His contributions to biochemistry are finding numerous applications, not only to foods but also to medical research and other fields of applied biochemistry.

Mr. E. O. Powell was with the Chemical Defence Experimental Establishment, Ministry of Supply, during 1941–46, and after a short period on industrial research re-joined the Ministry of Supply in the Microbiological Research Department in 1947. His versatility and insight have enabled him to make valuable contributions in such diverse fields as bacteriology, chemistry, mathematics and physics. He has done particularly important work in the development of micro-manipulative techniques for the study of individual bacterial cells, and also in bacterial genetics.

Mr. G. D. Robinson joined the Meteorological Office in 1936. He has made valuable detailed studies in atmospheric radiation and in the transfer of heat, momentum and water vapour between the ground and the air, and his published papers on this work are widely recognized as important contributions. These investigations of basic problems of energy exchange in the atmosphere are to be extended.

WORLD FEDERATION OF SCIENTIFIC WORKERS

ASSEMBLY AT BUDAPEST

The World Federation of Scientific Workers held its third assembly during September 12–14 in Budapest, at the invitation of the Hungarian Association of Scientists and Engineers. Thirty-five representatives of organizations of scientists in Bulgaria, Canada, China, Czechoslovakia, Denmark, France, Great Britain, Hungary, India, Poland and the U.S.S.R. attended the sessions. The proceedings were opened by the president, Prof. Frederic Joliot-Curie. The president's speech emphasized the need for scientists to inform the public of the useful things which science can provide, and to try to promote international exchanges of scientific literature and of personal visits as a contribution to improving international relations. Apart from organizational matters, the Assembly discussed certain questions of general interest to scientists. Reports on the salaries and conditions of work of scientists in various countries represented at the Assembly were presented. Special attention was devoted to the difficulties which are at present being experienced in connexion with exchanges of scientific books and periodicals. It is greatly to be hoped that an improvement in these exchanges can be achieved by the concerted action of all scientists in all countries. It was also decided to extend the publications of the Federation with the view of giving a presentation of the positive and constructive way in which science could contribute to the welfare of all peoples if it were freed from many of its present restrictions.

The resolutions passed by the Assembly made the following points: (*a*) that scientific workers everywhere should strive to secure the peaceful solutions of all international differences, so that less attention will be given to military preparations and more to the peaceful uses of science; (*b*) that governments could and should, by international negotiations, reach agreement regarding the prohibition of weapons of mass destruction; and (*c*) that academic freedom should be preserved and that the restrictions to which scientists are subjected should be reduced.

Laboratories and museums of all kinds were visited by delegates to the Assembly, and Hungarian scientists showed great pleasure in discussing scientific matters with their guests. To judge from the laboratories which have been recently completed and from those which are now in the process of building, it may be said that scientific institutions are rapidly developing and that large funds are available for this purpose. Many university teachers and research workers are engaged in writing text-books in the Hungarian language. The number of students in universities and institutes of higher education has increased seventeen-fold since 1939. During the same period the number of technical universities has increased from one to five, and the number of scientific books published each year by a factor of ten. Parallel with this great internal growth in education and research, there has developed a need for better contact with foreign science.

A novel feature of this Assembly was the holding of lectures on scientific subjects, given to the various Hungarian scientific societies, and they evoked great interest and discussion. Among the lecturers were: Prof. E. Aubel (France), on the mechanism and role of the biological reduction of nitrates; Prof. J. D.

Bernal (Great Britain), on (1) X-ray analysis of materials, and (2) the structure of proteins; Prof. K. Bratanov (Bulgaria), on the application of vegetative and sexual hybridization in stock-breeding; Dr. M. Degerbøl (Denmark), on prehistory and zoology; Prof. E. Grillot (France), on luminescence of crystalline minerals; Acad. L. Infeld (Poland), on the influence of Copernicus on the development of physics; Prof. Y. Le Grand (France), on recent researches on optical physiology; Acad. V. P. Nikitin (U.S.S.R.), on electrical welding; Sir Robert Watson-Watt (Great Britain), on the education of scientific workers; Dr. W. A. Wooster (Great Britain), on diffuse X-ray reflexions and the physical properties of crystals.

Excursions were arranged for the delegates to various centres of interest, in particular to the new steel town of Stalinvaros, to the ancient royal seat of Vesperen, to the district surrounding Lake Balaton and to a collective farm. Receptions were given by the Hungarian Academy of Sciences and by various delegations. Visits to the opera and ballet were also arranged. Just before the last session of the Assembly, a concert was given by the following distinguished musicians: Annie Fischer, Alexander Svéd, Ede Zathureczky, Mihaly Szèkely and Maria Gyurkovits. The hospitality extended to the guests was truly magnificent and they will long remember their stay on the island Margitszigit in the Danube.

Prof. F. Joliot-Curie (France) was re-elected president. Other officers re-elected included Prof. J. D. Bernal, Prof. C. F. Powell (vice-presidents), Dr. W. A. Wooster (treasurer), and Dr. E. G. Edwards (honorary secretary). The total membership of the scientific and technical organizations affiliated to the Federation has risen from 44,000 in 1951 to 136,770 in 1953, and it is distributed over thirteen countries.

W. A. Wooster

SYMPOSIUM ON GEOCHEMISTRY AT ZURICH

A SYMPOSIUM on geochemistry was held in Zurich during August 11–13 under the auspices of the International Union of Chemistry. It was presided over by Dr. M. Fleischer and by the local chairman, Prof. C. Burri, with Prof. T. F. W. Barth acting as secretary. More than sixty members, representing eighteen countries, were present. This meeting was the first international gathering of geochemists.

The material read at the symposium was divided into two groups: (1) reports relating to the problem of organizing, completing and making available geochemical data; (2) papers on geochemistry and allied subjects. The first group of communications included the following reports: by M. Fleischer on the geochemical work of the Geochemistry and Petrology Branch of the U.S. Geological Survey and on the progress of the revision of Clarke's "Data of Geochemistry" (Bull. 770, U.S. Geol. Surv.); by Marjorie Hooker on the progress made in the revision of Washington's "Chemical Analyses of Igneous Rocks" (Prof. Pap. 99, U.S. Geol. Surv.); by W. Muller on the geochemical work of Gmelin Institute; by P. Rosbaud on the publication of geochemical papers in *Geochimica and Cosmochimica Acta* (Pergamon Press, London); by K. Rankama on the compilation, revision and organization of current geochemical work; and by T. F. W. Barth on current geochemical research throughout the world. The second group comprised some twenty-five papers dealing with a variety of subjects, such as the geochemistry of certain elements, the distribution and abundance of elements in ground water, sea water, sedimentary and igneous rocks, the association of uranium with mineral hydrocarbons, the uranium content of deep-sea sediments, the geochemistry of petroleum and allied substances, the minerals of pegmatites, the composition and origin of meteorites, petrochemistry and petrogenesis, and the use of the periodic system of geochemistry. A fuller report of this meeting will be published in *Geochimica and Cosmochimica Acta*.

The meeting took place in the Mineralogical and Petrographical Institute of the Federal Technical College in Zurich by invitation of Prof. C. Burri and with the assistance of the staff of the Institute. After the meeting, a group of members of the symposium took part in an excursion to the Eastern Gotthard Massif (August 14–15), led by Prof. C. Burri.

During the symposium six members of the Commission on Geochemical Localization of the Elements of the International Union of Chemistry, who were present, met and, among other business, elected Prof. H. C. Urey as a member of the Commission in succession to the late Prof. P. Niggli, and Prof. C. Burri as an observer attached to the Commission. The composition of the Commission (subject to confirmation by the Committee of the International Union of Chemistry) is as follows: M. Fleischer (Washington), president; T. F. W. Barth (Oslo), vice-president; K. Rankama (Helsinki), secretary; and members, H. S. Brown (Pasadena), C. W. Correns (Göttingen), D. Guimaraes (Belo Horizonte), A. Holmes (Edinburgh), E. Raguin (Paris), S. I. Tomkeieff (Newcastle upon Tyne) and H. C. Urey (Chicago).

EFFECTS OF ATMOSPHERIC POLLUTION ON VEGETATION

ON September 9, the last day of the Liverpool meeting, Sections K (Botany) and K* (Forestry) of the British Association jointly discussed the increasingly important topic of the deleterious effects of chemical substances in the atmosphere on plant growth. It is all too well known that soot and gaseous products of combustion, such as sulphur dioxide, when released into the air over and around large cities and industrial areas, not only cause damage to buildings but also impair the health of animals and human beings. The damage to vegetation due to the same causes is less widely known but is very familiar to those who have to cultivate plants in forest, field, garden or glasshouse where atmospheric pollution occurs. In Great Britain the damage to glasshouse plants was especially noticeable during the unusually severe fogs that occurred during the winter of 1952–53. That the problem is not confined to Great Britain is shown by catastrophes such as those which occurred in the Meuse valley in Belgium in 1930, at Donora in Pennsylvania in 1948 and at Poza Rica in Mexico in 1950, in all of which localities much human illness and numerous deaths were shown to be due directly to short periods during which the atmosphere was more highly polluted than usual. A large-scale investigation of the damage to vegetation caused by atmospheric pollution in California was undertaken under the auspices of the Selby Smelter Commission, the conclusions of which were published in 1915. More recently, an international commission was appointed to investigate similar damage at Trail in British Columbia. The outcome of this research was made known in a book published in 1939 by the National Research Council of Canada.

Dr. C. R. Metcalfe (Royal Botanic Gardens, Kew), who opened the symposium by referring to the facts outlined in the paragraph above, then described how evergreens, and particularly conifers, in the Kew neighbourhood become stunted in growth owing to the deposition of soot on the leaves, and indicated that soot forms an adherent scum on the roofs of glasshouses, from which it can be removed only by vigorous washing soon after it has been deposited, or by chemical means if the deposit is one of long standing. Experimental work at Kew has shown, however, that the more acute symptoms of ill-health that so frequently appear in plants that have been subjected to a polluted fog are due not so much to reduction in availability of light as to the presence of toxic substances in the atmosphere. Examples of these acute symptoms are the shedding of flowers and leaves by begonias and many other plants that make a fine display during the winter months, the blackening and death of buds and flowers of certain orchids, notably *Calanthes*, the scorching of the foliage of cinerarias and primulas and the almost complete destruction of such plants as *Coleus blumei*, particularly the varieties 'Sunset' and 'Golden Ball'.

One of the most important of these toxic substances is sulphur dioxide. Treatment of susceptible plants with low concentrations of sulphur dioxide such as are known to occur in a London fog induces similar symptoms to those exhibited by the same species of plants during foggy weather, provided the atmosphere is sufficiently moist and the temperature sufficiently high. Other experiments have shown that the damage sustained is progressively more severe as the concentration of sulphur dioxide in the air goes up. Yet another series of experiments showed that sulphur dioxide can be removed from air by passing it through a column of sphagnum moss soaked in a solution of sodium carbonate, and that air purified in this way is no longer toxic to plants. Then again it was found that the damage done can be substantially reduced by protecting the plants with paper bags, which appear to have the power of adsorbing small quantities of sulphur dioxide. After pointing out that the experiments at Kew have led to conclusions concerning the toxicity of sulphur dioxide that agree except in a few minor particulars with the views expressed by investigators in Canada and the United States, Dr. Metcalfe ended his survey by referring briefly to practical remedies that can, or might be, used for alleviating the unhealthy symptoms exhibited by glasshouse plants in foggy weather. The amateur and small-scale cultivator should not despise the protection that can be afforded by a paper covering; cracks between panes of glass can be reduced to a minimum by stopping them up; chimneys from boilers should be so situated that they do not emit sulphur dioxide in the immediate vicinity of the glasshouses they are intended to heat. The temperature and humidity of the atmosphere should be reduced as much as the nature of the plants being cultivated will allow, and the value of this practice has repeatedly been demonstrated in greenhouses and by experimental methods in the laboratory. While chemical treatments in glasshouses to counteract the acids in the atmosphere have not shown much promise, it should not be impossible to construct special houses into which purified air can be introduced. Those concerned with town planning should choose sites for horticulture where atmospheric pollution is not likely to be severe. In this connexion the direction of the prevailing wind is most important. It is clear, however, that no single remedy can be found except by reducing and, if possible, eliminating the sources of pollution.

Mr. T. R. Peace (Forest Research Station, Farnham) raised the question of how near to urban areas can trees be planted with any prospect of securing an economic return on the outlay. It was pointed out that this important problem is still far from being solved. Mr. Peace also stressed the difficulty of distinguishing symptoms such as those of Dutch elm disease, or die-back of foliage and shoots caused by damage to roots in a heavy clay soil on one hand, and similar symptoms induced by a polluted atmosphere on the other. He described in some detail an occasion in June 1953 when considerable damage was sustained by trees on the Duke of Bedford's estate at Woburn. This damage occurred suddenly, and is believed to have been caused by the emission of fluorine from a neighbouring brickworks during a period when there was a wet fog, the relative humidity rising to 99 per cent at a temperature of 57° F. at 3.0 a.m., followed by a gradual rise in temperature and fall in relative humidity to 53 per cent by 3.0 p.m. on the following day. Conifers were more severely damaged than hardwood species. European larch was severely affected, the young shoots being killed outright. The distal ends of the current season's needles of Scots pine turned brown, and there was slight damage to Norway spruce, but Corsican pine sustained no damage at all. Similar damage occurred in the forest nursery as well as to more mature trees. Among hardwood species, slight damage to *Corylopsis* and *Rhus* was noted in the nursery, and *Pterocarya* shed its leaves.

Dr. J. K. C. Bleasdale (Botany Department, University of Manchester) described experiments in which seeds of various species of plants were buried in boxes of soil and grown in localities where the concentrations of pollution were known to be different. No visible effect of the pollution was noted in the plants raised in this way during the summer months, when the concentrations of pollution at all of the centres were relatively low; but, after the plants had passed through the winter, marked differences, corresponding to the degree of pollution, appeared in the health and vigour of the plants during the following spring. When hill pastures on farms in East Lancashire were ploughed and planted with selected strains of clovers and grasses from Aberystwyth, the increased pasture yields that were expected to accrue were not, in fact, realized.

Dr. Bleasdale agreed with the general belief that sulphur dioxide is one of the most noxious ingredients of smoke, and concentrations of from 0·5 part per million upwards are known to cause lesions on various types of plants. At concentrations below 0·5 part per million, lesions do not usually occur, and some of the previous investigators have claimed that growth is not seriously impaired below this critical concentration. Experiments in two small air-conditioned glasshouses in the Fallowfield district of Manchester showed, however, that prolonged treatment of the Aberystwyth strain of rye grass known as $S23$ with air containing concentrations of sulphur dioxide that ranged from 0·01–0·06 part per million gave a dry weight yield that was 45 per cent below that of plants grown in air that had been purified by passing it through a water scrubber. Some evidence was found, however, that the effect of polluted air may be masked if the rye grass is grown on soil of especially high fertility. The greenhouse experiments were supplemented by others in the field at nine different sites. These showed that plants such as rye grass, cabbages and wallflowers, in which active photosynthesis occurs during the winter months, are seriously stunted when grown in a polluted atmosphere, the reduced growth being most marked where the pollution is most concentrated. Dr. Bleasdale ended by referring to the competition for land between building and agricultural interests, and reminded his audience that the spread of suburbia combined with smoke pollution is reducing food production to an ever-increasing extent that might well become serious. Possible remedies would be to breed smoke-resistant varieties of food plants, and to apply chemicals to the plants to counteract the sulphur dioxide in the atmosphere.

These three contributions were followed by a lively general discussion in which reference was made to many aspects of the subject, including the action of a polluted atmosphere in inhibiting the development of lichens and mosses, the increasingly poor outlook for planting woodlands in the future, and the complex nature of the combined influence of soil conditions and air pollution on plant growth. Prof. H. G. Champion (University of Oxford), who has seen the damage to vegetation in the neighbourhood of the Trail smelting works in British Columbia, said that considerable improvement had been effected there by the introduction of remedial measures at the works. From the views that were expressed it is quite evident that, apart from the damage done by soot and other solid particles emitted into the atmosphere, there is general agreement that sulphur dioxide is one of the most important causes of damage to vegetation. It must not be overlooked, however, that certain American investigators have claimed that other chemical substances, such as oxidation products of olefines, are also responsible. The discussion undoubtedly served a useful purpose in focusing attention not only on the serious damage to plant life that sometimes occurs but also on the complex of physical and chemical factors that play a part in causing this destruction. A complete solution of the problem is not likely to be quickly achieved for economic reasons; but it is to be hoped that success will come gradually through the combined endeavours of engineers, meteorologists, chemists and botanists. C. R. METCALFE

COMPARATIVE PHILOLOGY AND POLYNESIAN STUDIES

By PROF ALAN S. C. ROSS

University of Birmingham

PHILOLOGY (or linguistics) consists of two parts, usually called descriptive linguistics and comparative philology, respectively. The latter is technical and esoteric (therefore its nature is not easy to describe shortly), whereas the former is of a nature altogether more obvious.

The main task of descriptive linguistics is, in fact, the answering of the question: What is the best, or even, what is a good way to describe language; or, to describe a particular language? It is very clear that the 'normal' answer to this question—namely: Languages may best be described in the terms in which Latin is conventionally described—is valueless when applied to the majority of languages. That is to say, 'Latin' grammar, with its sharp distinction between, for example, verb and noun, and its system of declension and conjugation, cannot afford us a frame for describing a language such as Tahitian, which has no trace of declension or conjugation and, apparently, has one massive part of speech corresponding to the Latin verb, noun, adjective and adverb taken together.

Some philologists consider that no satisfactory answer to the question: How may a language be described? has yet been given. Others, however, think that they have given an answer and have established, in several schools already somewhat at war with each other, the subject known as structural linguistics. The main centres of this new subject are, first, many American universities, and then the Universities of London, Paris and Copenhagen.

The second branch of linguistics, comparative philology, makes statements of which the following are the three main types: (1) 'English and German are related languages'; (2) 'the English word *stone* is philologically identical with the German word *stein*'; (3) 'an Anglo-Saxon long *ā* becomes a Modern English long *ō* (as in AS. *stān* MnE. *stone*'). Statements of all these types are technical and entirely non-obvious; the learner of comparative philology must be prepared to expend a good deal of hard work before he can expect to understand them.

The 'axiom' underlying statements of the first kind is simple to state; it is merely that 'Two languages are defined as related if, and only if, they were once one language'. Thus French and Spanish are related because, and only because, they were both once Latin. Developing this axiom in an obvious manner, it is easy to establish the concept 'Family of Languages'; for example, English, German, Dutch, etc., form the Germanic family of languages.

Comparative philology, in its modern sense, came into being at the beginning of the nineteenth century. One of its main tasks has been the arranging of the languages of the world into families of related languages, and great progress has been made in this field. To-day, the thousands of languages in the world stand arranged into hundreds of different families (with no relationship proved to subsist between any pair of the families). The next—and incomparably the more laborious—task is the production of all possible statements of the second and third types for each family. Only when this has been done can the comparative philology of a family be said to exist.

Even in pre-1914 Germany (where the subject flourished most), the number of comparative philologists has always been small, in comparison with the number of, for example, natural scientists. It is therefore scarcely surprising that, in the century and a half which has elapsed, it has not been possible to bring into being (still less to complete) the comparative philology of more than seven families, namely: (1) Indo-european (to which, for example, English, Latin and Russian belong); (2) Uralian (for example, Finnish, Hungarian and Samoyede); (3) Semitic (for example, Hebrew and Arabic); (4)

Turkish–Mongol–Tungus (sufficiently described by its name); (5) Bantu (for example, Zulu); (6) Dravidian (for example, Tamil); (7) Indonesian (for example, Malay).

The establishment of the comparative philology of the remaining families of the world may well take many centuries of research work, and the prospect has recently been darkened by the almost complete gulf which now separates the new and fashionable structural linguistics from the old-established comparative philology—a gulf which, in extreme cases, may extend to an actual despising by the structuralist of the rigid disciplines of comparative philology.

Comparative philology is of immense value and importance to other subjects, for, it must be remembered, it is unsafe to make even the simplest statement involving the history of a word (such as, that it is a borrowing from another language, or, that earlier it had a different meaning) without reference to a specialist in the relevant comparative philology. Such statements are, alas, often made without such reference and they are, naturally, always without value. Although comparative philology is so esoteric, its *results* are often much appreciated by non-philologists; to take two examples, common enough in Britain, the classical scholar uses such results with profit for Homeric criticism, and the results of English place-name study are of great value to the historian—though both are usually entirely ignorant of even the nature of comparative philology.

As already stated, the outlook for the establishment of a comparative philology for families of languages still without it is rather poor. There is, however, one exception to this statement and the purpose of the present article is to direct attention to it. There is, in fact, one family the comparative philology of which, at the moment untouched, could be established by a very small group of scholars in half a life-time's work. This family is Polynesian.

The reason why it is precisely Polynesian that, of all the 'untouched' families of the world, is in so exceptionally favourable a position, is that Polynesian is closely related to Indonesian, a family the comparative philology of which is in an extremely advanced state, by reason of the labours of generations of Dutch scholars. Furthermore, the Polynesian languages are few in number (Maori, Tongan, Hawaiian, Samoan and Tahitian are the principal ones), the relationship between them is very close (Hawaiian and Tahitian are scarcely more 'distant' than are German and Dutch), and, finally, their relationship to the Indonesian languages is also fairly close, being of somewhat the same order as is the relationship between Lithuanian and Russian. The Balto-Slavonic family consists of two branches—Slavonic (with, for example, Russian, Czech and Bulgarian) and Baltic (comprising Lithuanian, Lettish and Old Prussian); if we were to imagine that the comparative philology of Slavonic had been thoroughly worked out but that that of Baltic was still untouched (which is, of course, not the actual case), then this hypothetical state of work to be done would give us a very fair picture of the actual state existing in regard to Indonesian (worked out) and Polynesian (untouched).

It seems, then, desirable that a comparative philology of Polynesian should be inaugurated forthwith. How may this task best be accomplished?

Polynesian falls naturally under the head of 'Pacific Languages'—which term I here use to comprise (1) the Polynesian family; (2) the Melanesian family; (3) the very many different families of New Guinea; (4) the many different families of Australia. To-day, the study of Pacific languages is everywhere linked with either anthropology or structural linguistics. Neither of these linkings is likely to be of much value to the proposed comparative philology of Polynesian. It would not be desirable to attempt to turn either an anthropologist or a structuralist into a comparative philologist; anthropologists rather naturally tend to regard linguistics as a subordinate subject and I have indicated the attitude of the structuralists above. Furthermore, neither an anthropologist nor a structuralist is likely to have received any grounding in the disciplines of comparative philology. It seems, then, that the proposed comparative philology of Polynesian had better be essentially independent of both the subjects mentioned (though it might well have liaison with and, later, offer help to both anthropologists and structuralists).

The proposed study must, of course, be centred in some university or institute and not more than six choices present themselves.

(1) In London the School of Oriental and African Studies, which has recently had so many new linguistic developments (for example, as concerns Africa and South-East Asia), has shown a slight interest in Pacific languages. But this interest has been purely descriptive, indeed structuralist. Comparative philologists may regret that the languages in the Pacific field selected for study by the School have been mostly Melanesian (for example, Gilbertese), a family which offers no hope of the establishment of a comparative philology for many lifetimes, instead of Polynesian, which offers a real and present hope of such establishment. But it may be that, from the point of view of the structuralist, the Melanesian languages are more interesting.

(2) After a terrible record of neglect, first of its own aboriginal languages, then, even less excusably, of New Guinea languages from the end of the penultimate war onwards, Australian university life has at last begun to take a modest interest in these languages. Rather naturally, the study seems to be at least slightly subordinate to anthropology; but this is not the main difficulty, which is simply the enormous number of different languages requiring study. Australian philologists will surely be occupied for many decades with the plain task of describing them.

(3) At Honolulu there is a long-established tradition of Polynesian studies at the Bernice P. Bishop Museum. However, this interest is, in the main, anthropological and, furthermore, the supreme dominance of structuralism in the United States would be likely to militate against the establishment of any new comparative philology.

(4) In Paris two Pacific languages are admittedly taught at the École des langues orientales vivantes; these are Wailu (the major language of New Caledonia, a Melanesian language) and Tahitian (a Polynesian language). The instruction and interest here are, however, confined to the imparting of a practical knowledge of these languages to French people going to these areas, and there is no sign of any interest in comparative Polynesian philology, or even in any other Polynesian language.

None of the first four choices, neither London, Honolulu, Paris nor an Australian university, thus seems in any way especially suitable as a venue for the proposed study of comparative Polynesian philology. The remaining two choices deserve, however, much more serious consideration.

(5) In Holland the comparative philology of Indonesian has a long and dignified tradition (the literature is, naturally, almost entirely in Dutch) and it is on Indonesian that the proposed comparative philology of Polynesian is, of course, to be based. At first sight, then, some Dutch university would seem particularly suitable for the establishment of such a study. But two points could be urged against this choice. First, Governments are not usually prepared to devote money to the languages of areas in which they have no territorial interest, and Holland has none in Polynesia. Second, who can forecast what deleterious effect the present rift between Indonesia and Holland may not have upon these studies hitherto flourishing in Holland ?

(6) There remains only New Zealand. Here there has for long been an interest in Maori studies. At the moment this interest is oriented entirely in the direction of either anthropology or (by reason of American interest) of structural linguistics. But there seems no reason why an equal, or surpassing, interest in comparative Polynesian philology could not be built up. New Zealand has always been eminent in what is essentially a branch of comparative philology, in that, for its size, it has produced a quite undue proportion of scholars distinguished in Anglo-Saxon and Middle English (though it has, admittedly, exported most of them to Britain). New Zealand has another advantage: only here, in the whole of Polynesia, is there, at the moment, any likelihood of there existing a native speaker of a Polynesian language (namely, Maori) with sufficient preliminary education for it to be possible to turn him into a comparative Polynesian philologist.

It seems, indeed, that one of the New Zealand universities would be the ideal venue for the setting-up of the unit, which, it is proposed, will establish the comparative philology of Polynesian. The practical details of such a setting-up remain for consideration.

In the first place, it may be pointed out that the unit could well be a small one. A professor, two lecturers and a secretary could probably accomplish the whole task in a decade. By modern university financial standards, the expenditure for such a unit would not be all too great. But funds for three ancillary purposes would have to be provided.

(1) *Library*. Philology, much more than medicine and natural science, requires old books as well as new; nowadays, it is not possible to obtain the out-of-print books of any philology by second-hand purchase and, in the main, copies must be obtained by photographic aids (photostats, 'Copycats', microfilms, etc.). But, from the financial point of view, Polynesian is, in this respect, very fortunately placed, for its literature is, comparatively, very scanty. An initial expenditure of £1,000, plus an annual grant of £100, would probably be sufficient for the acquiring of a substantial Polynesian collection (the comparable figures for a Balto-Slavonic collection might well be £15,000 and £500).

(2) *Travelling*. The smallness of the library expenditure would, however, be more than offset by the high travelling expenses. Since Polynesian languages can only be learnt by speaking, it would clearly be desirable for members of the proposed unit to spend much time travelling in the Pacific. Furthermore, they would have to visit the Indonesianists in Holland from time to time (and on these European visits they would, of course, also have to keep in touch with other philologists in Europe).

(3) *Publication*. Naturally, the results of the establishment of the comparative philology of Polynesian would, in due course, have to be published. Probably a series of monographs, in conjunction with a periodical, would best meet the case here. Here perhaps it would be desirable to envisage the nature of the publications required. An adequate descriptive and comparative apparatus for an Indo-european language (and we must accept the same standard for Polynesian also) might consist of: (*a*) descriptive 'grammar' (declension, conjugation—in application to different parts of speech) and 'syntax' (uses of the same, word-order, etc.); (*b*) the complete catalogue of all things such as (for Modern English) 'Anglo-Saxon *ā* becomes Modern English *ō* (AS. *stān* MnE. *stone*)', mentioned above, and the historical *raison d'être* of all that is set out under (*a*) above; (*c*) a dictionary into the same, or some other language (in the latter case, with inverse dictionary also); (*d*) an etymological dictionary (that is, for English, the setting-out of all possible equations of Type English *stone* = German *stein*, mentioned above).

Thus, A. Heusler, "Altisländisches Elementarbuch" might serve as a (small-scale) model for (*a*) and (*b*) combined (in respect of Old Icelandic), the "New (or Oxford) English Dictionary" as a model for (*c*) and (*d*) combined (in respect of English).

In addition to the 'advanced' apparatus (*a*), (*b*), (*c*) and (*d*), there should be an 'elementary' apparatus also—something to help the beginner on his way to more serious methods of study (such as speaking); the standard Gaspey–Otto–Sauer grammars might serve as examples of this.

Owing to the nature of Polynesian languages (no declension or conjugation, virtually no parts of speech), there would be great difficulty in writing descriptive grammars of Type *a* (above). As already mentioned, it is not practicable for them to be written on the 'Latin' method—as can readily be observed from those already written. It may be doubted, too, whether the structuralists are in fact going to give practical help here. There seem to be only two possible solutions to the difficulty. First, to model the grammar on that of ancient Indonesian, by now well elaborated by the Dutch philologists, that is, to regard the phenomena of, for example, Tahitian as decay-products of those of Old Javanese; second, to write no grammars at all, but to relegate all that would be in them to the dictionaries. A study of the world's great dictionaries—for example, "New English Dictionary" (note, for example, the head-words *So* adv. and *Set* vb.), H. G. Liddell and R. Scott, "Greek–English Lexicon", J. and W. Grimm, "Deutsches Wörterbuch", "Groote woordenboek der nederlandsche taal", and "Svenska Akademiens ordbok"—will undoubtedly convince the reader that this method is practicable. The proposed 'Primers' would, on this second method, merely consist of text, literal translation and glossary modelled on the dictionary.

If this second method were adopted (and it is, I feel, the better one) the problem of publication becomes greatly simplified and is reduced to the following scheme.

(I) For each Polynesian language separately: (1) a dictionary, into English, modelled on the "New English Dictionary" and with inverse index; (2) a primer.

(II) For the aggregate of Polynesian languages, taken together: (1) a comparative phonology, that is, something setting out all results of the Type AS. *stān* : MnE. *stone* (mentioned above); W. Streitberg, "Urgermanische Grammatik", might serve as a model; (2) an etymological dictionary; A. Walde and J. Pokorny, "Vergleichendes Wörterbuch der Indogermanischen Sprachen", might serve as a model.

There is, finally, the question of selecting and training the proposed unit for the establishment of the comparative philology of Polynesian. All its members must, of course, be thoroughly conversant with comparative philology, and this end is probably best attained by their having passed through some quite conventional school of philology (such as 'English Language', 'French Language' or Sanskrit, as taught in Great Britain). Next they must have an adequate training in Indonesian, and this can only be gained by at least three years residence in Holland (and, possibly, some time in Indonesia). It is much to be hoped that at least one member of the unit will be a native speaker of Maori (one who had gone through an 'English Language' training in a New Zealand university would be ideal); it might well be desirable to invite a distinguished Dutch Indonesianist to spend at least some time as another member.

CHEMICAL RESEARCH LABORATORY, TEDDINGTON

REPORT FOR 1952

THE report of the Chemistry Research Board, signed by the chairman, Prof. E. L. Hirst, and the report of the director of the Chemical Research Laboratory, Teddington, Dr. D. D. Pratt, make up the contents of "Chemistry Research 1952", which has recently been published*. To these reports are appended a list of more than fifty papers submitted for publication during the year, and lists of the staff of the Laboratory, of metals held by the Pure Metals Committee, of standard substances available and of species in the National Collection of Industrial Bacteria. Both reports refer to the improvement in working conditions through the occupation of the new Radiochemical Building in May and of the Microbiological Buildings in November, thus easing the overcrowded conditions in the main building and enabling the construction of a mass spectrometer and research on high-temperature corrosion of metals by hot flue gases and by boiler-water to be commenced. Nevertheless, the Board records the opinion that the scientific staff is still too small in relation to the programme, though it merely expresses the hope that additional staff will be provided "when circumstances permit".

The Board's report again stresses the value of the work of the Corrosion of Metals Group. The value of the electrical capacitance method of measuring the rate of water uptake of a paint film on immersed metal has been further investigated with anti-corrosive paints and an anti-fouling paint, and an apparatus has been constructed in which specimens can be subjected to controlled amounts of spray solutions, infra-red and ultra-violet radiations. Studies of the mechanism of corrosion inhibition by potassium chromate and sodium benzoate using radioactive tracer techniques indicate that the former is more firmly held by the metallic surface. Bacteriological examination of a clay soil in which the expected attack on buried pipes had not occurred revealed the presence of a species of *Actinomyces* toxic to sulphate-reducing bacteria. Examination of a waterlogged clay soil from a site at Hungate, York, in which ancient buried iron particles were excellently preserved in spite of the presence of sulphate-reducing bacteria, anaerobic conditions and the appropriate *p*H range for bacterial activity, showed that the activity of the bacteria was suppressed by concentrations of tannin of 0·01 per cent and upwards. In conjunction with the British Iron and Steel Research Association, an inquiry has been initiated into the incidence of buried water-pipe failure in Britain and the efficacy of cathodic protection. Other investigations have included a study of the effect of pressure on the rate of oxidation of copper at 100–250° C. and the use of film-stripping and microchemical techniques in a study of the influence of surface condition on the low-temperature oxidation of mild steel, while an investigation of the effect of small amounts of salts and particles left on metal surfaces subject to different treatments in metal-finishing processes has shown that blistering of paint on sheet-steel articles may be caused by salt contamination of metal surfaces arising in treatments prior to painting. The importance of humidity in the corrosion of steel has been confirmed in tests carried out in collaboration with the Institute of Petroleum Protective Panel, and good protective value has been obtained by temporary protective coatings in which corrosion inhibitors are incorporated in thixotropic suspensions of inorganic earths: although soft and easily removed when no longer required, these coatings do not flow from the protected surfaces on storage.

The Inorganic Group has completed its work on the elimination of arsenical impurities from germanium; further work has been carried out on the production of dicalcium phosphate from phosphate rock by the action of nitric acid followed by ammoniation, and studies of the action of sulphuric acid on an apatite from Uganda indicate that the apatite can be fairly readily converted to phosphoric acid provided the concentration of the sulphuric acid is carefully controlled. The study of the reaction between ferric oxide and ammonium sulphate has been continued; a search was commenced for possible sources of selenium from waste materials, and spectrochemical methods for detecting and estimating this element were being sought, as well as methods for determining phosphorus in organic compounds which can be applied to the determination of this element in ion-exchange resins. In collaboration with the Radiochemical Group, the carrier technique, used for the micro-estimation of thorium, has been adapted to the direct determination of tantalum and niobium separately in ores. The chromatographic process for the separation of these metals that has been worked out by the Radiochemical Group has proved simple and accurate for a wide variety of products, while the quantitative separation of palladium, platinum, rhodium and iridium by a chromatographic process has been practically completed, and preliminary experiments have shown that bismuth can be separated chromatographically from a solution containing nitric acid. Extension of the work on the adsorption and elution of complex cyanides of gold, copper and iron with 'Amberlite

IRA 400' resin to the complex cyanides of nickel, cobalt, zinc and silver has led to the development of a method for the separation and recovery of these metals from solutions derived from the cyanidation of auriferous ores. New equipment constructed during the year includes apparatus for determining automatically the life of ion-exchange resins on continuous re-cycling with different solutions, and an automatic scanning device for filter-paper strips on which the separation of metallic salts containing radioactive tracers has been effected. The device provides a permanent quantitative record of the activity distribution. A scintillation counter has also been devised consisting essentially of a lead and brass housing for a photomultiplier with a heavy brass slide arranged so that a small silica cell can be brought easily and accurately in front of the photomultiplier cathode.

Some changes were made in the organization of the Organic Group during the year: the two Organic Intermediates Sections were amalgamated, and a new Standard Samples Section split off from the Purification and Measurements Section. Work on the introduction of functional groups into polystyrene resins through the chloromethylation reaction will in future be continued in the High Polymers Group, but the Organic Intermediates Section will continue to prepare substances that by polymerization or condensation will furnish new resins containing functional groups. An initial study of stearic acid containing palmitic acid by the differential vapour-pressure method, using an apparatus with mercury as the manometric liquid and a tap-less device for pressure equalization, showed that as little as 0·1 per cent of palmitic acid could be estimated. Measurements of the vapour pressures of pyridine bases continued, and the purification of *iso*-octane, methyl*cyclo*pentane, methyl*cyclo*hexane, ethylbenzene and *o* cresol has been followed spectroscopically. A method of estimating *iso*nicotinic acid in the presence of nicotinic, picolinic and dipicolinic acids has been developed in which a Spekker absorptiometer is used with an Ilford filter 604. Quantitative analyses have been made by infra-red absorption spectroscopy of mixtures of picolines, 2 : 6-butidines and 2-ethylpyridine. In collaboration with the National Physical Laboratory, the Organic Group has made progress in a programme for determining the heats of combustion of organic compounds by improvements in chemical technique and in the calorimeter, and the heats of combustion of four pyridine bases have been measured at 25° C. under standard conditions. The isotope dilution method has been applied to the determination of naphthalene in a high-temperature coal tar and in the evaluation of the efficiency of naphthalene-recovery plant. A study of the mechanism of the Kolbe–Schmitt reaction has been commenced, and the benzoin reaction with terephthaldehyde has been reinvestigated. Attempts have been made to prepare selective ion-exchange resins of well-defined constitution by introducing suitable functional groups into polymers. The addition of carbon monoxide, acetylene and α-picoline has brought the list of standard substances available for distribution as reference specimens to thirty-six items, and the temperature and pressure of acetylene at its triple point have been determined.

In view of the outstanding performance of polyvinyl alcohol films as semi-permeable membranes in non-aqueous systems and the specific recommendations of the High Polymers Committee that studies on the fundamental factors controlling the semi-permeability of polymer films should be initiated and that membranes suitable for use in aqueous systems should be investigated, the effort of the High Polymers Group devoted to work on membranes has been increased. In the absence of additional staff, it has been necessary to stop work on covalent reactions of functional groups in polymers and to reduce that on ion exchange. The major items in the research programme of the Group are new studies on the ion-exchange and allied properties of polymers and studies on the semi-permeability of polymer films: with both topics much attention is being given to possible industrial applications of new materials or processes developed during the work. The programme of research on the use of surface-sulphonated polystyrene in ion-exchange chromatography has been completed, and work was commenced on the preparation of insoluble resins containing functional groups capable of reactions other than ion exchange. Investigation of the applications of polyvinyl alcohol membranes has shown that these membranes considerably extend the scope and accuracy of somatic pressure measurements on polymer solutions, and their impermeability to solute and ready transfer of solvent permit the use of simple unsymmetrical osmometers.

The Microbiology Group has intensified its fundamental investigations on sulphate-reducing bacteria. These have included studies of the hydrogenase activity of *Desulphovibrio desulphuricans*, of its carbon metabolism, including the pyruvate metabolism by which certain strains can grow without sulphate, its variability and its viability. Investigations of the formation of sulphide in the water bottoms of petrol-storage tanks led to the recommendation that the water should be changed frequently and sodium chlorate added where necessary, as this inhibits both sulphate reducers and the corrosion of steel. A continuous method for the cultivation of sulphate-reducing bacteria is being employed by a team from the Chemical Research Laboratory at the Microbiological Research Department, Porton, of the Ministry of Supply, and a marked increase in the rate of sulphate-reduction has been achieved by the use of a suitable nutrient medium. Further development of the microbiological production of sulphur depends largely upon the availability of adequate supplies of suitable fermentable wastes as sources of carbon. The National Collection of Industrial Bacteria now maintains 620 strains, of which 52 were added during the year.

On the advice of the Pure Metals Committee, nickel, rhenium, thallium and titanium have been added to the stock of high-purity metals. Investigations on the oxidation of steel at moderately high temperatures have been commenced with special reference to the possible improved resistance of steels for boiler superheater tubes, and advice on the control of corrosion in heat-exchange systems resulted in successful treatment of a system at the Atomic Energy Research Establishment, Harwell, and of cooling coils in fermenter vessels used in the manufacture of penicillin and streptomycin. Advice has also been given on the choice of materials for the construction of a water-filtration plant in Australia, for heating coils in oil tankers and for a new sewerage scheme in Lancaster, and on the protection of wharf steelwork at Kuwait in the Persian Gulf and the prevention of corrosion in lining pipes in artesian wells in Madras.

HYDRATION STRUCTURE OF DEOXYRIBONUCLEIC ACID AND ITS PHYSICO-CHEMICAL PROPERTIES

By DR. BERTIL JACOBSON*

Department of Chemistry and Chemical Engineering,
University of California, Berkeley, California

RECENTLY, various helical structures have been proposed for deoxyribonucleic acid[1-3]. That suggested by Watson and Crick[3] is of special interest, since it is shown here to have a remarkable similarity with the structure of the tetrahedral water lattice. This similarity makes it possible to explain the great tendency of deoxyribonucleic acid to interact with water, and also to interpret several strange properties of its solutions. Hammarsten[4], thirty years ago, suggested in a general manner that these properties were due to the state of hydration of the deoxyribonucleic acid molecules; the details of his explanation can now be formulated more exactly.

It has been postulated that water has a regular quasi-crystalline structure only slightly different from that of ice[5]. In studying the details of the ideal water lattice, it has been found here that the interstitial volume has a spatial arrangement like that of helices parallel to the a-axes, as illustrated in Fig. 1. Helices of certain different dimensions exist, and their pitch is a multiple (n) of the water lattice units in the a-axis direction and thus amounts to $4\cdot514 \times n$ A. at 0° C. and approximately $4\cdot74 \times n$ A. at 25° C. (calculated using as thermal coefficient of linear expansion the value 2×10^{-3} deg.$^{-1}$). Pitches with certain multiples of those given are also possible. The integer n also denotes the number of coaxial helices of the same pitch and the same diameter that can be coiled around the same a-axis. The diameter of the interstitial helices is fixed for each value of n. If a cylindrical or helical section of water is removed from the ideal water lattice parallel to any of its three a-axes, a cavity is formed, the surface of which has oxygen atoms arranged in a helical manner similar to that of the interstitial helical space. The oxygens are free to form hydrogen bonds with a macromolecule placed in the cavity.

The Watson and Crick structure for deoxyribonucleic acid contains two helical polynucleotide chains coiled around the same axis with the phosphates on the outside and the basic groups from the two chains joined together on the inside of the helix. There are ten residues per turn and the pitch is 34 A. The outer diameter is about 20 A. and the inner diameter[6] about 12 A.

As is seen in Fig. 2, the Watson and Crick structure fits well into the water lattice. The outer helical envelopes of the polynucleotide chains through their phosphoric groups are the same as the $n = 7$ helix in the water lattice. The diameter in the water lattice is 21·8 A. and the pitch is 33·2 A. The inner helical envelope does not correspond to a simple water lattice helix but to one with $n = 3\cdot5$ with a double pitch. In the plane perpendicular to the a-axis, the fitting is excellent, as is seen in the upper part of Fig. 2. The ten nucleotide residues per turn along the outer helical envelope might be able to form hydrogen bonds (if the fitting in the a-axis direction allows it) with every other of the twenty (18–22 depending upon how the helix is placed) hydrogen-bonding positions in the water lattice. Corresponding to the ten basic groups along the inner helical envelope there are ten (or twelve) hydrogen-bonding positions in the water lattice. In the plane perpendicular to the c-axis and in the direction of the a-axis (lower part of Fig. 2), there are seven water lattice units per ten residues in the polynucleotide helix. This poorer fitting in this direction is to be expected, since the length of the deoxyribonucleic acid molecule varies with the ionic strength of the solvent[7]. From studies of the equatorial X-ray reflexions of the deoxyribonucleic acid molecule, it has been assumed that the two helices should be displaced from each other by about three-eighths of the fibre-axis period[8]. From considerations of fitting with the water structure, the displacement could be any fraction of seven, and three-sevenths or two-sevenths might also agree with X-ray data.

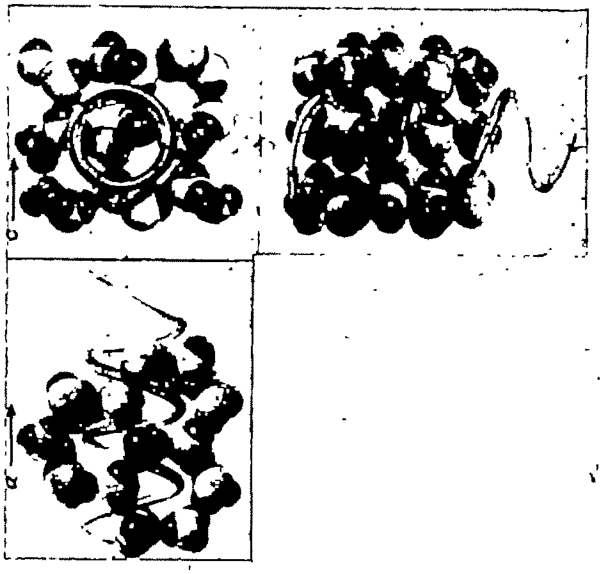

Fig. 1. Ideal water lattice viewed from three mutually perpendicular positions. The interstitial space has a helical shape as indicated by the rubber spiral

Light-scattering and streaming birefringence measurements have both shown that the deoxyribonucleic acid molecules contract on addition of small amounts of electrolytes[7]. The maximum reduction in length was 30–40 per cent, occurring when the ionic strength was increased from 0 to 2×10^{-3} N. It is highly probable that the Watson and Crick model is the structure of the contracted molecule. If the contracted form is now assumed to be exactly 30 per cent shorter than the extended form, the latter would have a distance between the residues along the helical axis equal to the dimension of the unit cell in the water lattice, $a = 4\cdot74$ A. The extended form would then fit very well into the water lattice. Most of the physical properties indicate this is actually the case, as will now be discussed.

Previously, and independently of these findings, it was concluded from streaming dielectric investigations[9] on electrolyte-free solutions that the surface of the deoxyribonucleic acid molecule had the property of being able to order the water molecules to form a more regular ice-like structure. The mechanism can be explained on the following basis. Due to structural similarities and also to hydrogen-

bonding between the deoxyribonucleic acid macromolecules and the water lattice, the thermal vibrations of the lattice are reduced. This leads to a more regular structure and therefore to an increase in hydrogen hybridization, resulting in an increased dipole moment of the water molecules[5]. Since this might be a possible explanation of the fact that ice has a higher dielectric constant than water (at low frequencies), it also explains the very high dielectric constant observed in electrolyte-free solutions of deoxyribonucleic acid[9,10]; the magnitude of this constant can scarcely be accounted for in any known way other than a structural change of the water of hydration of the macromolecules. This ordering effect of the water lattice must be effective over distances many times the diameter of the deoxyribonucleic acid molecules.

The contraction of the deoxyribonucleic acid molecules upon addition of small amounts of electrolytes explains why the osmotic pressure[4], the viscosity[4] and the dielectric constant[10] all decrease rapidly when the ionic strength is increased from 0 to 10^{-3} N. The extended form of the deoxyribonucleic acid molecule (as occurs in salt-free solutions) has, as proposed above, a structure on the surface that fits excellently into the water lattice and therefore orders a large volume of the surrounding water to a more regular ice-like structure. When the molecules contract on the addition of very little salt, the fitting over large distances along the surface of the macromolecule is impaired, and from the ice-like hydration shells water which was previously bound is made free, a process that apparently reduces the concentration of the hydrated macromolecular aggregates. This results in a reduced osmotic pressure. Also, since the regularity of the water lattice is decreased its rigidity is diminished[11], causing a decrease in viscosity. Furthermore, the reduced lattice order results in a smaller dielectric constant.

Time effects of the properties of deoxyribonucleic acid solutions can be explained as arising from a mutual slow adaption of macromolecular and water lattice structures leading to a slow building up or breaking down of the 'crystallized' ice-like hydration shells. The decrease in viscosity and in dielectric constant[9] on streaming is probably the result of such a breakdown due to the applied velocity gradient.

In certain electron micrographs of dried solutions the molecules are arranged in an irregular hexagonal manner[12,13]. This can be explained as a long-range ordering effect by the water lattice. Since the deoxyribonucleic acid molecules tend to become parallel with any of the three a-axes in the water lattice, a triangular, rhomboidal or hexagonal arrangement is probable.

Watson and Crick claim that their model suggests a copying mechanism for the genetic material. If their proposed mechanism is correct, the water structure must be of ultimate importance for the separation process of the two polynucleotide chains. The ten hydrogen-bonding positions in the water lattice can easily take over the hydrogen bonds between the basic groups in the helical chains and thus enable a separation with small amounts of energy. Further, the excellent fitting with the water structure in the extended form, which possibly might be a straight-chain molecule, also makes a separation of the two chains possible with low energies.

ACCELERATION OF FLOWERING IN PARTIALLY VERNALIZED GRAIN OF PETKUS WINTER RYE BY SUBSEQUENT TREATMENT AT HIGH TEMPERATURE

By D. J. C. FRIEND and Prof. F. G. GREGORY, F.R.S.

Research Institute of Plant Physiology, Imperial College of Science and Technology, London

It is now well known that the acceleration of flowering brought about in winter rye by exposure during germination to periods of low temperature can be in part annulled by exposure to temperatures above 15° C. given immediately after vernalization. The degree of reversal of vernalization achieved depends (1) on the duration of the low-temperature treatment, (2) the temperature-level and duration of the subsequent heat treatment. The vernalized condition becomes progressively stabilized and irreversible as the duration of low temperature is prolonged, and after twelve weeks of vernalization subsequent heat treatment has no effect on flowering[1].

In the course of further work in 1952 on the relationship between the degree of devernalization achieved by varying durations of high temperature following immediately after different periods of vernalization, a new effect of temperature was discovered. In these experiments longer periods of heat treatment than hitherto were employed—up to six weeks at 20° C. and 25° C., respectively—and it appeared that such prolonged heating of partially vernalized grain led to an intensification of vernalization.

As the growth of the grain was restricted by limiting the water content during treatment to 50 per cent of the oven-dry weight, it is clear that these effects are independent of growth during germination of the partially vernalized grain. Further, it has been shown (unpublished data) that neither Petkus spring rye nor unvernalized or fully vernalized winter rye are affected in their flowering behaviour by similar heat treatments. The effect is thus confined to partially vernalized grain under conditions where free growth is constrained by water shortage.

Tables 1 and 2 present experimental data carried out with plants grown in sand culture, under conditions of constant seventeen-hour day-length. The effect on flowering is shown both by final leaf number and the days to anthesis counted from planting out at the end of the temperature treatment.

The data in Table 1 show that treatment at 20° C. for periods of 3–6 weeks has led to no devernalization, but on the contrary a marked acceleration of flowering has resulted, as may be seen by comparison with the values for the control set. The effect is evident both in leaf number and time to anthesis. The longer the exposure to 20° C. the greater the acceleration of flowering. The final leaf number of the set given 20° C. for six weeks does not differ significantly from that of grain vernalized for nine weeks and unheated (10·2 ± 0·3). Short periods of heat treatment at 20° C. following upon six weeks of vernalization are known to have a devernalizing effect[1]; but with the shortest duration in this experiment (three weeks) no devernalization occurred.

The series treated at 25° C. show marked devernalization after exposure for six and twelve days; but with three and six weeks treatment the devernalization effect has disappeared, and these sets do not differ in flowering behaviour from the unheated controls.

In Table 2 a similar set of data are presented for plants grown from grain vernalized for four weeks before being given heat treatment.

Table 1. Effect on Flowering of Petkus Winter Rye Vernalized for Six Weeks and then Immediately Exposed to Temperatures of 20° C. and 25° C. for Varying Durations

Temperature of heat period	Duration of heat treatment in days	Mean final leaf number	Mean days to anthesis
20° C.	42	10·9 ± 0·3	63·3
,,	35	10·3 ± 0·2	63·1
,,	28	12·6 ± 0·6	73·4
,,	21	11·9 ± 0·3	71·6
25° C.	42	15·9 ± 0·7	103·8
,,	21	15·5 ± 0·6	104·0
,,	12	18·9 ± 0·5	145·6
,,	6	17·1 ± 0·4	121·3
Unheated control vernalized six weeks	0	15·4 ± 0·5	105·6
Unheated control vernalized nine weeks	0	10·2 ± 0·3	

Note. The number of replicates varies from 40 to 48

Table 2. Effect on Flowering of Petkus Winter Rye Vernalized for Four Weeks and then Immediately Exposed to Temperatures of 20° C. and 25° C. for Varying Durations

Temperature of heat period	Duration of heat treatment in days	Mean final leaf number	Mean days to anthesis
20° C.	42	18·2 ± 0·7	134·4
,,	35	15·7 ± 0·7	110·3
,,	28	17·9 ± 0·6	139·7
,,	21	18·1 ± 0·6	148·7
,,	12	20·6 ± 0·4	179·5
25° C.	42	20·7 ± 0·5	172·9
,,	21	21·1 ± 0·3	183·7
,,	12	21·3 ± 0·2	192·6
,,	3	21·4 ± 0·4	188·5
Unheated controls vernalized four weeks	0	19·6 ± 0·4	162·6
Unheated controls vernalized six weeks	0	15·4 ± 0·5	

Note. The number of replicates varies from 38 to 46

The set given 20° C. shows a marked devernalization when heated for twelve days; but continued heating removes the effect and an acceleration of flowering is obtained after three weeks, and this becomes more marked as the heat treatment is prolonged, as comparison with the unheated controls shows. The behaviour of the set heated for five weeks is similar to that of unheated grain vernalized for six weeks, and thus the effect of heat is equivalent to that of an extra two weeks at low temperature.

At 25° C. short periods of heat treatment have resulted in devernalization greater than that following 20° C., but with prolongation of heating devernalization is absent, and both final leaf number and days to anthesis approach the value for the unheated controls.

The effect of a prolonged period at high temperature in accelerating flowering of partially vernalized grain is in agreement with deductions from the schema suggested by Purvis and Gregory[2]. It is necessary to assume that the postulated thermostable end-product of the vernalization reaction (substance *B* in the schema) increases autocatalytically and that the rate of this reaction increases with temperature. Evidence that the end-product of vernalization increases in the plant has already been put forward[3] and is deduced from the fact that removal of the apex of the main shoot and of several successive generations of branches fails to destroy the vernalized condition of the plant, which flowers normally.

The effects of high temperature following a restricted period of vernalization are thus twofold: (1) a devernalization due to removal of a labile intermediate (the reaction *A*, *A′* in the schema); (2) the self-perpetuation of the stable end-product (*B* in the schema). The total effect of a heat treatment after partial vernalization will thus depend upon the relative rates of these two processes.

A further experiment has shown that there is no effect of high temperature on the flowering of spring or fully vernalized winter rye, from which it would appear that in these cases flowering is not determined by the concentration of substance *B* but must be controlled by subsequent photoperiodic reactions.

Further work to elucidate these effects is in progress, and a full account will be published in due course.

A Host-Protein Component of Influenza Viruses

EXPERIMENTS designed to unmask deeper antigenic components of influenza viruses by heat degradation of their type-specific surface antigens yielded evidence of relationship between virus types *A* and *B* based upon their possession of a common antigen. The antigen concerned was found to be almost indistinguishable from a component of the host tissues (chick embryo) in which the viruses were propagated, which at once aroused suspicion that it might be merely contaminant material adsorbed on the virus. The presence of an antigenic component in purified virus preparations of types *A* and *B*, which was also demonstrable in normal allantoic fluids, was first reported by Knight[1], who used a precipitation test with hyper-immune rabbit sera and viruses purified by differential centrifugation. It has been pointed out that reliance upon centrifugation for virus purification is open to the objection that centrifugation merely selects particle size and density, and it has been shown by Knight[2] himself that the normal allantoic fluid antigen is of similar size to the influenza viruses.

Attempts have been made in this laboratory to obtain irrefutable evidence that the host component is not an adsorbed contaminant but an integral part of the virus structure.

*PR*8 virus from infected allantoic fluids has been purified by four successive cycles of adsorption and elution using human red cells. This process is regarded as being essentially enzymic and therefore highly specific. The eluates, both untreated and heat-treated sufficiently to ensure destruction of the specific surface antigens, have been used as the antigens in cross-serological tests by means of a micro complement-fixation test[3]. Antisera against untreated virus were prepared by immunizing rabbits with infected allantoic fluids; but for the production of antisera against heat-treated virus, fourth-cycle eluates were used in order to ensure complete absence of antibodies against contaminant material. The rabbits were given two spaced injections and bled at the height of the secondary response, a technique which avoids the cross-reactions concomitant with hyper-immunization.

The results of four representative experiments from a very large number giving consistent results are shown in Table 1. They reveal the existence of a relatively thermostable antigen, distinct from the labile specific antigen, in this type *A* strain of virus. The thermostable component is demonstrably present in either untreated or heat-treated virus.

It has not been possible until very recently to prepare fourth-cycle eluates of type *B* virus (*Lee* strain) of adequate potency; consequently satisfactory heated-*Lee* antisera have not been available. Preliminary experiments, however, with first- or second-cycle reagents leave no doubt that a similar relatively thermostable antigen is present in the type *B* virus. Although full reciprocal cross-tests have not yet been done for the reason stated, the recently produced fourth-cycle *Lee* eluates have been tested against the *PR*8 antisera. The results included in Table 2 indicate the identity, or extremely close similarity, of the thermostable antigens of the two virus types *A* and *B*. Table 2 also includes the results of tests which show that the heated *PR*8 antisera will fix complement with aqueous extracts of normal chorioallantoic membranes. Antisera from rabbits immunized with such heated extracts, however, although potent against the homologous antigen, give at best only slight fixation with the heated virus antigens. This indicates a slight but significant immunological difference between the membrane and viral antigens, and is cogent evidence against the criticism that the latter represent merely adsorbed contaminant material.

Table 1. CROSS COMPLEMENT-FIXATION REACTIONS BETWEEN HEATED AND UNHEATED 4TH-CYCLE ELUATES OF *PR*8 VIRUS AND CORRESPONDING RABBIT ANTISERA.

The normal chorioallantoic membrane antigen would appear to be of the Forssmann type. It is extractable with 96 per cent alcohol and will withstand boiling; also the antibodies of the homologous antiserum can be readily absorbed out with sheep red cells. Attempts to extract the viral antigen in a similar manner are beset by the difficulty of preparing sufficient bulk of highly purified virus; but work to this end is now under way.

Another approach to the problem has been the disintegration of purified *PR*8 virus by multiple cycles of freezing and thawing with the object of releasing additional demonstrable thermostable antigen[4]. Serial samples removed during the course of such treatment show progressively less antigen for a number of cycles; but in some experiments a subsequent sudden and sharp rise has occurred. We interpret this phenomenon as the expression of the shifting balance between degradation of antigen and its release by disruption of the virus particle.

The results so far obtained do not indicate conclusively whether the thermostable antigen represents

host material incorporated as an intrinsic part of the virus particle, or merely adsorbed so firmly on the particle that it is able to pass through four adsorption–elution cycles. The slight immunological difference between the chorioallantoic membrane extract and viral antigens, the fact that the former antigen is considerably more thermostable than the latter antigen and the phenomenon of antigen fluctuation during the process of virus disintegration, lend support to the former alternative.

Development of Virus in the Cell Nucleus

THE nuclear polyhedral viruses of insects offer a unique opportunity for the study of virus behaviour in the cell. By knowing that the dominant focus of virus activity is in the cell nucleus, there is the advantage of being able to concentrate attention on a small and very definite site. The characteristic rod-like shape of the virus particles is an additional advantage in facilitating their recognition.

We have examined under the electron microscope a long series of very thin sections of nuclei of the silkworm (*Bombyx mori*) at various stages of infection, and by this means have built up a fairly convincing picture of the way the virus seems to arise in this restricted area. This study arose out of the discovery, in formalin-fixed diseased nuclei, of a peculiar structure which we have called the 'nuclear net'[1], and the sequence of events seems to be briefly as follows. At first, prior to the formation of the nuclear net, the nucleus becomes greatly enlarged. Next, the chromatin bodies begin to clump together to form the nuclear net; at this stage no virus bodies are visible. A little later, the rods begin to form and can be seen protruding from the central chromatic net and from the peripheral chromatin. The apparent metamorphosis of material of the chromatic net to virus rods is extremely interesting. At very high powers the net can be seen to consist of a fibrillar structure, and these fibrils seem to thicken to the normal diameter of the virus. The virus rods are then apparently pushed out into the nuclear ring zone (Figs. 1 and 2).

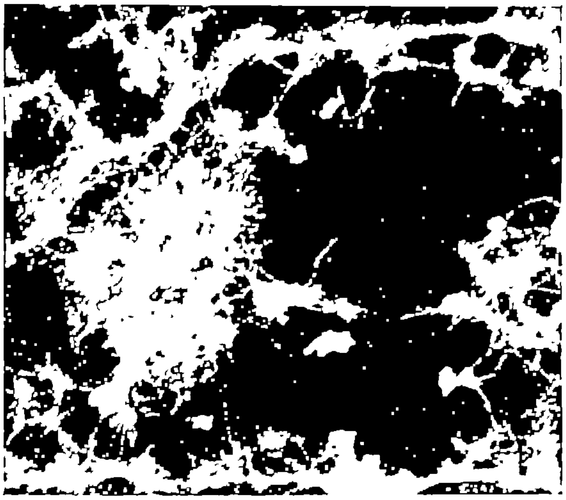

Fig. 1. Very thin section of a diseased nucleus of *B. mori*; the chromatic mass is to the left centre of the nuclear ring zone. Note the virus rods protruding from the central mass and the peripheral chromatin. (× c. 16,000.) *Photo: S. Vernon Smith*

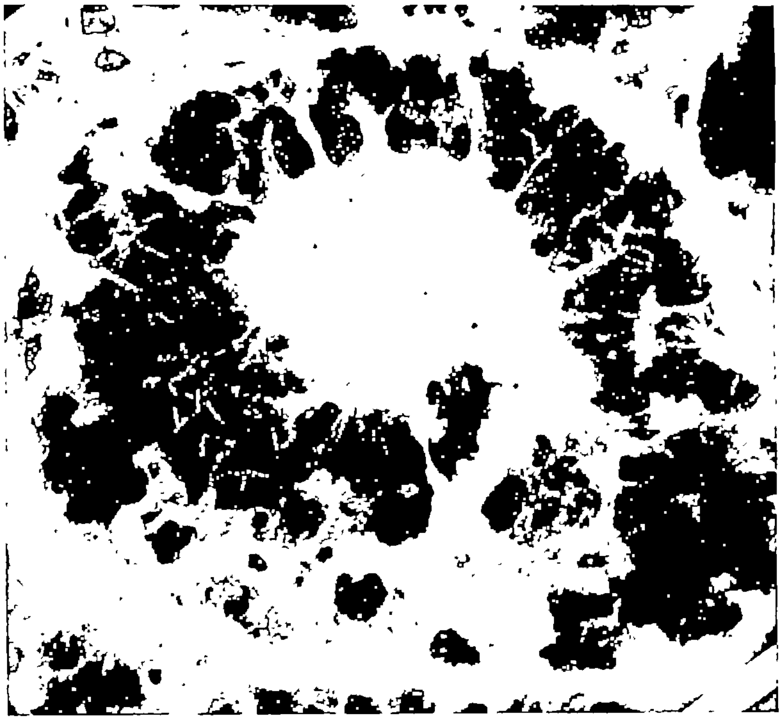

Fig. 2. Similar to Fig. 1. The ring zone contains many free virus rods without surrounding membranes; note the bunches of rods protruding from the chromatin. (× c. 16,000.) *Photo: S. Vernon Smith*

Following this, many free virus rods accumulate in the nuclear ring, but there are no membranes around the rods such as occur inside the polyhedral crystals (Fig. 2). In the next stage the polyhedral protein begins to accumulate in the ring zone and to aggregate around the virus rods. In some of our micrographs it is possible to see the rods actually being embedded in the polyhedral protein, giving a sculptured effect.

In the final stage, the polyhedra form and almost fill the nucleus. At this stage there are no free virus rods or loose polyhedral protein left in the nuclear sap. From our examination of a large number of sections and from the manner in which the virus rods appear to form in the chromatic masses, we are drawn to the tentative conclusion that this virus behaves much less like an organism than a differentiated product of altered cell metabolism.

Growth Cycle of Ectromelia Virus in Mouse Liver

MANY workers have found that the multiplication of viruses occurs in definite cycles, each involving several stages, namely, adsorption and entry to host cell, a loss of part or all of the infectivity, a 'lag' phase during which no new infective virus can be demonstrated, a period of intracellular rise in infectivity, and finally release of this virus followed by invasion of a fresh population of susceptible cells. We have studied the intracellular multiplication of ectromelia virus in mouse liver, using intravenous inoculation and assaying the infective titre of the liver at intervals. We have found that over a range of inocula from 10^{6} to 10^{10} *LD*50 about 30 per cent of the inoculum is adsorbed to the liver in five minutes. Inocula of 10^{9} *LD*50 infect practically all the liver cells within five minutes, as measured by a histological method[1].

We have found that the multiplication of ectromelia virus also occurs in definite stages. After adsorption there is a rapid fall in infectivity to less than 1 per cent of the initial (five-minute) titre, then a lag period, followed by a rise back to the five-minute titre. Next there is a period of little multiplication followed by a rise in titre, then this last cycle is repeated. This is illustrated in Fig. 1, in which each point represents a pool of two or three mice. When two or more points on a growth curve are obtained from a single mouse the same stepwise rise in titre is found. Such growth curves are obtained with an average dose of one or more *LD*50 per liver cell, so infection of previously uninfected cells would be quite insufficient to account for the final rise in titre. It appears that multiplication takes place at some intracellular site and the infectious units so produced initiate multiplication on further intracellular sites in the same cell, resulting in the final increase in titre.

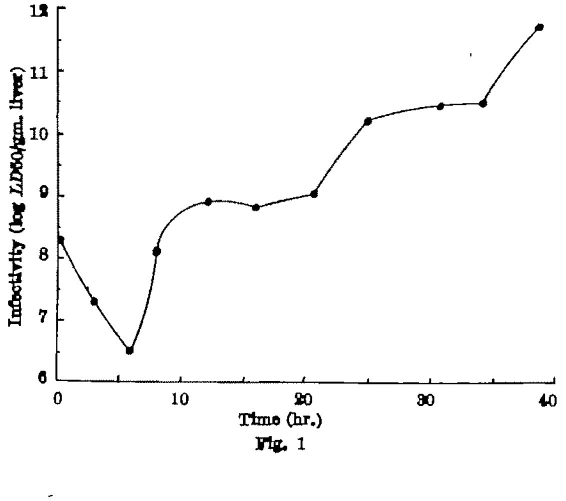

Fig. 1

Furthermore, we have been able to infect liver cells with as many as 20 *LD*50 per cell, assuming 10^{8} liver cells per gram of liver. Even with this multiplicity of infection there is no auto-interference, that is, all twenty particles multiply independently of each other, and reach as high a titre as do lower initial doses.

These two findings would suggest that the fundamental virus-synthesizing centres must be sought at a sub-cellular level.

This work will be reported more fully in a subsequent paper.

Contribution of Side-Chains to the Infra-Red Spectra of Proteins: the 6·5-μ Band

THE strong bands at 3 μ, 6 μ and 6·5 μ which dominate the absorption spectra of proteins in the fundamental region, and which have been observed as well in N-monosubstituted amides and in synthetic polypeptides, have been attributed to vibrations of the peptide links between the amino-acid residues forming the structural backbone of the protein molecule[1]. It has been established, however, that, in most proteins, side-chains carrying ionizable groups are joined to the polypeptide backbone, and that at the isoionic point the protein exists in the form of dipolar ions. Of the ionizable groups which have been identified, carboxyls occur in the greatest number and may be expected to contribute significantly to the absorption processes in the spectral region of interest.

We have studied the absorption of the carboxyl groups of synthetic polymeric acids and ampholytes in solutions of heavy water (which permit examination of the spectral region 5–8 μ [2]) and have found that the band at 5·87 μ (1,703 cm.$^{-1}$), characteristic of the un-ionized group, disappears upon addition of base, and is replaced by a very intense band at 6·40 μ–6·45 μ (1,560–1,550 cm.$^{-1}$), and by another, less prominent one at 7·10 μ (1,410 cm.$^{-1}$). These changes in the absorption spectrum, which for polymethacrylic acid are shown in Figs. 1*A* and 1*B*, are in agreement with observations on simple fatty and amino-acids, in which the 6·4-μ and 7·1-μ bands have been attributed to the unsymmetrical and symmetrical valence vibrations of COO^{-} respectively[3]. Although in proteins the 6·4-μ band coincides with the strong peptide absorption at 6·5 μ, it has been possible to establish the contribution of carboxylate groups by working in heavy-water solution, in which the hydrogens in the peptide linkages are completely exchanged for deuterium and the band characteristic of the peptide vibration is shifted to longer wavelengths, probably 6·95 μ (1,440 cm.$^{-1}$). As is evident from Fig. 1*C*, deuteration of isoionic bovine plasma albumin does not eliminate the absorption in the 6·5-μ region—a band remains, centred at 6·4 μ; upon addition of deuterium chloride to the solution, however, this band disappears and is replaced by a shoulder on the low wave-length side of the 6·08-μ band, as shown in Fig. 1*D*. Simultaneously, the

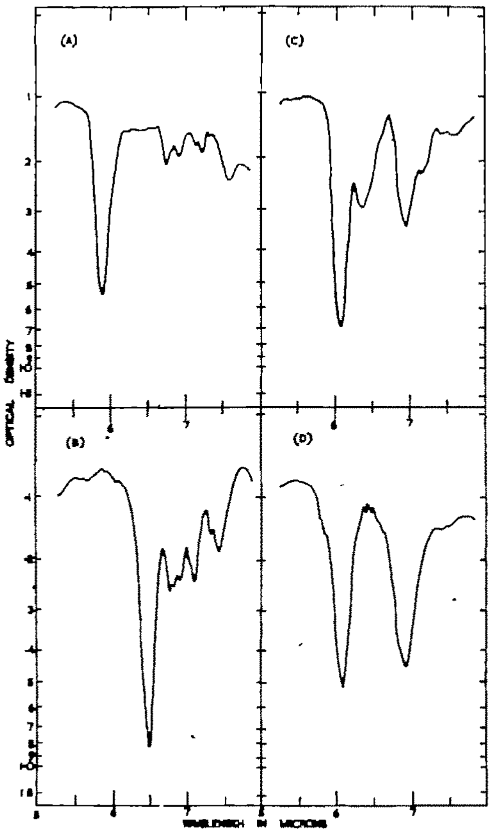

Fig. 1. Infra-red absorption of (*A*) polymethacrylic acid in heavy water solution (6·4 per cent); (*B*) polymethacrylic acid in 0·4 *N* sodium deuteroxide; (*C*) isoionic bovine plasma albumin in heavy water solution (7·6 per cent); (*D*) isoionic bovine plasma albumin in 0·3 *N* deuterium chloride

shoulder at 7·13 μ, observable in isoionic solutions, also disappears. Addition of an equivalent amount of sodium deuteroxide again restores the bands at 6·4 μ and 7·1 μ. These shifts must be attributed to the changes in the ionization of the carboxyl groups concomitant with *p*D changes in the protein solution.

It is apparent that the envelope of the 6·5-μ band of undeuterated proteins will, on the low wave-length side, depend upon the state of ionization of the protein molecule. Conclusions concerning changes in the arrangement of polypeptide chains, based upon the frequency criteria of Ambrose and Elliott[4] as applied to this region, must therefore be treated with reserve unless it can be demonstrated that the contribution of carboxyl groups has not been significantly altered.

This investigation, a fuller account of which will be presented in a subsequent communication, was supported by Contract *N6 onr*-23224 with the Office of Naval Research and Contract *DA*-44-109-*QM*-1037 with the Quartermaster Corps.

Aspartate–Glutamate Transaminase in a Red Halophilic Bacterium

LITTLE information is available on the metabolism of the red halophilic bacteria, although they represent a most interesting ecological group of organisms and are of some importance in the packing, pickling and curing industries. In a survey of their respiratory activity it was observed that resting cells did not oxidize readily the common carbon compounds usually employed, but actively oxidized glutamic, aspartic and other amino-acids. This observation prompted further study, in the course of which it was discovered that these bacteria possessed an active aspartate–glutamate transaminase system. The results of this work with *Pseudomonas salinaria*[1] are presented in this preliminary report.

Cells of *P. salinaria* were harvested from a three-day culture grown on the medium devised by Katznelson and Lochhead[2] but modified to contain glycerol as the carbohydrate addition. Cells were washed once with 0·025 *M* phosphate buffer, *p*H 8·0, containing 15 per cent sodium chloride. Since intact cells of this organism readily oxidized glutamate and aspartate, transamination was conducted in nitrogen. Cell-free preparations, on the contrary, did not oxidize these two acids and transamination could be accomplished equally well in air or nitrogen. All such tests were conducted with conventional Warburg respirometers at 37° C.

The aspartate–glutamate transaminase was indicated qualitatively by demonstrating the production of glutamate in a reaction mixture containing a source of enzyme and the sodium salts of α-ketoglutaric and aspartic acids as substrates. Glutamate was identified chromatographically with 75 per cent ethyl alcohol as the solvent. Enzyme activity was evaluated quantitatively by determining formation of oxaloacetic acid by the aniline-citrate procedure[3].

The aspartate–glutamate transaminase in *P. salinaria* proceeded optimally at *p*H 8·0, yielding a distinct glutamic acid spot on paper and, after a suitable incubation period, the expected amount of a β-keto-acid, presumably oxaloacetic acid, as indicated by the amount of carbon dioxide produced on tipping aniline-citrate into the main compartment of the reaction vessel.

The effect of sodium chloride on the transaminase activity was determined by centrifuging equal quantities of a cell suspension (of standardized turbidity) and resuspending in 0·025 *M* phosphate buffer (*p*H 8·0) containing the required concentration of sodium chloride. When suspended in salt-free buffer or one containing 1, 2 or 4 per cent sodium chloride the cells plasmoptysized completely in a matter of seconds. In the presence of 8 per cent sodium chloride there was also noticeable deterioration in cell structure, but not at 16 per cent sodium chloride. The results presented in Fig. 1 suggest that between 4 and 8 per cent sodium chloride is required for optimal enzyme activity.

This transaminase system was partially resolved into a coenzyme and protein moiety by ammonium sulphate fractionation[4]. Cell-free preparations were obtained by plasmoptysizing cells in buffer containing 4 per cent sodium chloride. The transaminase was removed from solution by saturation with ammonium sulphate and was redissolved in 4 per cent sodium chloride buffer. Data presented in the accompanying table show that at least partial resolution of the enzyme was effected by dialysis of the redissolved

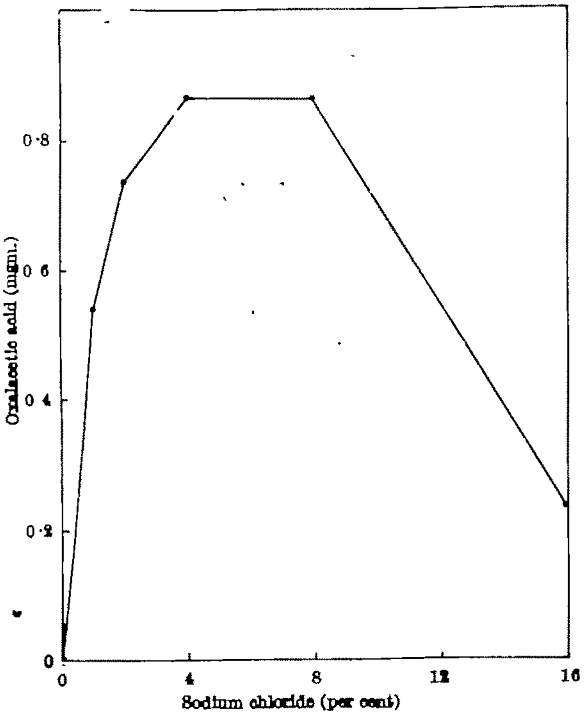

Fig. 1. Effect of sodium chloride on aspartate–glutamate transaminase

precipitate against 16 per cent sodium chloride buffer. The activity of this preparation was doubled by the addition of the ammonium salt of pyridoxal phosphate. Activity of the preparation dialysed against salt-free buffer could not be restored by additions of pyridoxal phosphate and 4 per cent sodium chloride. It would appear, therefore, that this enzyme system possesses a minimal requirement for sodium chloride below which there is an irreversible loss of activity.

Structure of Wool

In earlier investigations of the structure of wool[1], two fractions were obtained by peracetic acid – ammonia treatment of the keratin. One fraction was found to be soluble in weak ammonia, leaving behind an insoluble residue of 5–10 per cent in non-medullated specimens. The following is a report of an investigation by X-ray and infra-red methods of such specimens obtained under controlled conditions of extraction. Slurries of the insoluble residue were dried down to form films so that, wherever possible, X-ray and infra-red studies could be made on the same samples. Films of the soluble wool keratin were also made which were capable of investigation by the two methods.

The validity of the original investigations has been questioned by Woods *et al.*[2], who concluded from a repeat of the experimental work that the insoluble fraction was not in the β-form but rather that this modification was caused by an α → β transformation of the original insoluble material when the extraction temperature was raised from 20° C. (approximately) to 40° C. It was therefore suggested by these workers that the differences noted by one of us (F. H.[3]) in the original experiments were due to an artefact.

In earlier infra-red work on proteins by Elliott[4] it has been shown that the wool fibre in its normal state contains a certain proportion of β-protein, although it is well known that the structure of wool has in the past been identified by X-ray methods solely with the α-protein structure. On the other hand, in the case of feather keratin[5], which gives a β X-ray diagram, there is clear evidence from its infra-red spectrum of the presence of an α-component in the structure. Thus the infra-red method gives an overall picture of the polymer structure, whereas the X-ray method confines itself essentially to the crystalline components of the system.

In the present work the infra-red observations were made in the region of the strong carbonyl stretching frequency at 1,600–1,700 cm.$^{-1}$. Ambrose and Elliott[6] have shown that a slight shift in this frequency takes place in going from an α- (1,656 cm.$^{-1}$) to a β- (1,630 cm.$^{-1}$) protein configuration. Thus, using these frequencies as the basis of identification of the α- and β-components of the specimens, it has been shown that: (*a*) In the film made from the soluble keratin there is only evidence of an α C=O stretching frequency (1,656 cm.$^{-1}$). This is shown on curve I of Fig. 1. (*b*) The X-ray diagram of this film gave an α-keratin configuration, and when filaments were made by extrusion of this material an orientated α-diagram comparable with that from natural wool was obtained (see Fig. 2).

In the case of the insoluble fraction, several additional observations of interest were noted. (*a*) For films of the insoluble residue made at 20° C. the infra-red spectrum showed a peak at 1,656 cm.$^{-1}$ characteristic of the α-form with a definite shoulder at 1,630 cm.$^{-1}$ characteristic of the β-form (see Curve II, Fig. 1). (*b*) When the film was heated to 80° C. in water, after drying there was no change in the relative intensity of the β-shoulder of the curve.

The X-ray diagrams of these specimens, however, showed wide differences in the crystalline components of the films. (*a*) At 20° C. the characteristic α X-ray diagram was not present, but the 4·65-A. β-protein reflexion was diffuse. With increase of temperature of extraction up to 30° C., however, the

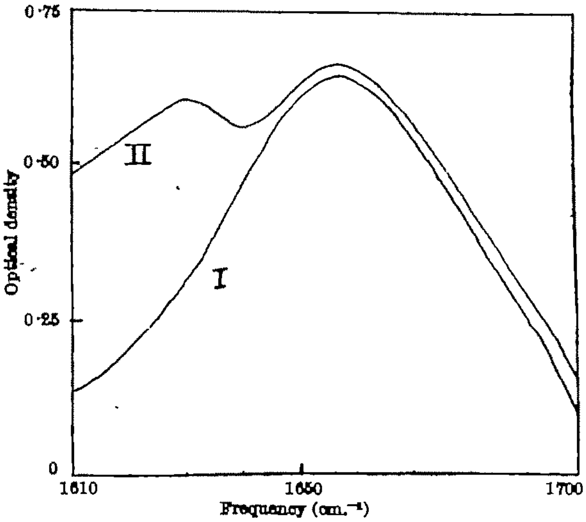

Fig. 1

β-line became more defined. In the case of a film heated in water for ten minutes at 30° C. and afterwards dried the diffraction diagram gave a strong ring at 4·65 A. (b) Further, it has been shown (private information, P. Alexander) that the photograph of orientated fragments of the insoluble phase of wool gave a resolution of the 4·65-A. diffuse arc around the equator of the X-ray diagram. (c) In an experiment in which the slurry was extruded through a fine jet to form a pseudo-filament the filaments examined were found to have little or no orientation, but there was a transformation of the diffuse ring into a sharp and strong reflexion at 4·65 A. This would suggest that stressing the insoluble particles may lead to a crystallization of the β-phase. Further, in some of the original work carried out by one of us the separation of the slurry was achieved by centrifuging, and it is possible that this method of extraction of the slurry at 20° C. may well transform the β-phase into a crystalline component, as did apparently the extrusion process in the experiment described above.

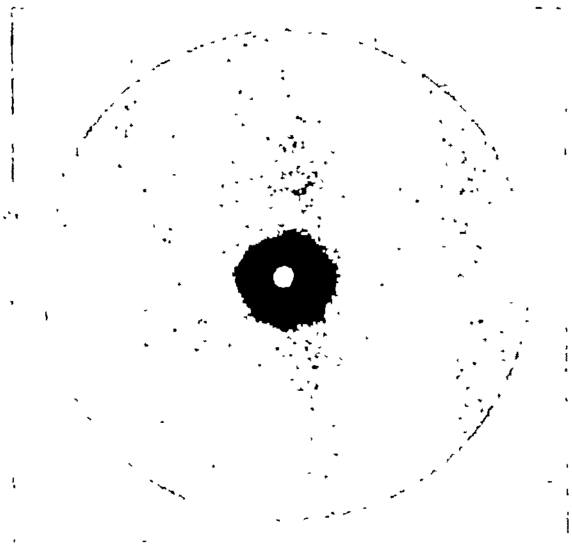

Fig. 2. X-ray diagram of regenerated keratin from wool showing oriented α-structure

From these experiments, therefore, it would appear that the presence of the β-phase in the insoluble fraction of wool is a true phenomenon as measured by the infra-red method. Further, its relative proportions under the conditions cited are constant in any one sample; but its unambiguous identification from an X-ray diagram may depend upon (1) its degree of crystallization which can be modified by its manipulation, or (2) the orientation of particles of the insoluble material in certain cases.

Further work is at present in progress, and a more detailed presentation of the results will be given in another place.

This work was financed by the Wool Textile Research Council, to which two of us (T. P. M. and G. J. W.) are indebted for fellowships.

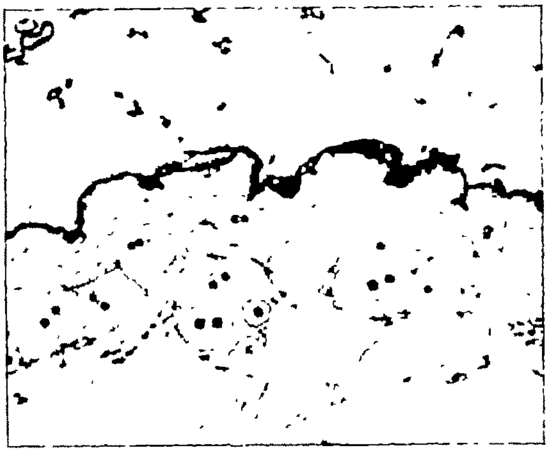
Demonstration of Keratin with Aldehyde-Fuchsin

Pearse[1] reported that keratin is demonstrated by the Schiff reagent after oxidation with performic acid. He suggested that the technique would be improved if a chromogenic agent were found which reacted readily with sulphonic and sulphinic acids but not with other basophilic groups such as carboxyl groups.

Studies[2,3] in our laboratory on the staining reactions of Gomori's aldehyde-fuchsin[4] with various mouse tissues have shown that this stain has a strong affinity for tissue elements with a relatively high sulphur content. Mast cell granules and cartilage matrix, tissue elements containing highly sulphated mucopolysaccharides, stain intensely with aldehyde-fuchsin without previous oxidation. Cystine-containing elements, keratin and beta-cell granules of the islets of Langerhans, react strongly with the stain after oxidation with periodic acid or acidified permanganate. Since it is known that sulphonic groups may be produced by the oxidation of cystine[5], it appears that aldehyde-fuchsin has an affinity for acid sulphur groups such as the sulphuric groups of sulphated mucopolysaccharides and the related sulphonic groups produced by the oxidation of cystine.

In the work described above, the tissues were oxidized for five minutes with periodic acid solution *B*[6] or for two minutes with a mixture of equal parts of 0·5 per cent sulphuric acid and 0·5 per cent potassium permanganate. After either of these procedures, the stratum corneum of epidermis and pancreatic beta-cell granules give a strong reaction with aldehyde-fuchsin. It is found, however, that both these elements are stained more intensely after oxidation with acidified permanganate than after periodic acid oxidation. In neither case do the hair shafts stain except for a weak reaction in the cuticle after permanganate oxidation.



Photomicrograph of section of mouse skin. The stratum corneum of the epidermis and the hair shafts are deeply stained. Mast cells and elastic fibres are also demonstrated. Bouin fixation, oxidation with peracetic acid for two hours, aldehyde-fuchsin, fast green F.C.F. as counter-stain. (× 100)

In later experiments, it was learned that, after oxidation for thirty minutes with acidified permanganate, the cortex of the hair external to the skin surface stains with aldehyde-fuchsin though the hair shafts within the skin remain unstained. On oxidation for one to two hours with peracetic acid, prepared as described by Pearse[1], both the stratum corneum and the hair shafts throughout their length are intensely stained. With shorter periods of peracetic acid oxidation, the stratum corneum reacts strongly while the hair shafts do not. These results suggest that the 'hard' keratin of the hair shaft is less susceptible to oxidation than the 'soft' keratin of the stratum corneum.

The greater resistance of hair shaft keratin to oxidation is also indicated by the results of Pearse[1]. He found that after performic acid oxidation the keratin of the hair shafts reacts more strongly with the Schiff reagent than does the keratin of the stratum corneum. As a possible explanation of this he noted that, since the Schiff reaction for keratin seems to depend upon the presence of the less oxidized sulphinic acid (alanine-β-sulphinic acid), it would appear that the further oxidation to the Schiff negative sulphonic acid (alanine-β-sulphonic acid) is more complete in the stratum corneum than in the hair shaft.

The results reported here show that aldehyde-fuchsin serves as an effective reagent for the demonstration of keratin after peracetic acid oxidation. The only tissue elements, besides keratin, which are stained in skin by this technique are mast cell granules and elastic fibres. There is none of the diffuse coloration which may occur with the Schiff reagent.

Birefringence and Elasticity in Keratin Fibres

THE long-range extensibility of wool and hair has been the subject of numerous investigations, in which changes in tension[1], X-ray diffraction pattern[2] and infra-red dichroism[3] have been studied during extension. The extent to which the elasticity of hair and wool may be considered rubber-like, and the interpretation of the changes in the X-ray diffraction pattern, have been the subject of considerable controversy[4]. In an attempt to cast new light upon the molecular mechanism responsible for the remarkable elastic properties of keratin fibres, the changes in birefringence extension have now been investigated and are described in this preliminary account.

Non-medullated human hairs of approximately circular cross-section were selected and degreased by successive extractions with cold petroleum ether. The extensions were performed in water on the stage of a polarizing microscope by means of a simple micro-extensometer. The extension ratio, α (stretched length/unstretched length), was determined by observing the separation, as measured with an eye-piece micrometer, of particles of carbon deposited on the scales of the hair. Retardation, Γ, was measured with a Berek compensator. Birefringence is defined as Γ/t, where t is the diameter of the fibre; but it is necessary to reduce the observed values to a common density, ρ_0, as Poisson's ratio is known to vary during extension. The observed birefringence must be multiplied by a factor $\sqrt{\rho_0/\rho}$, and since $\rho_0/\rho = \alpha t^2/t_0^2$ all values were reduced to a common density by use of the relation $n_\parallel - n_\perp = \Gamma\sqrt{\alpha}/t_0$, where t_0 is the initial diameter. Typical birefringence/extension curves are given in Fig. 1. Although the initial value of the birefringence differs from fibre to fibre, the fractional increase at any extension shows little variation. It is assumed in the following discussion that the observed birefringence is intrinsic, as no form birefringence has been detected by the usual methods[5]. The problem of impregnating keratin fibres with organic solvents of widely different refractive indices presents special problems, and is to be investigated further. Load/extension curves obtained under similar conditions of loading are given for comparison in Fig. 1.

Approximate birefringence values of 0·012 for the α-helix[6] and 0·032 for the pleated-sheet[7] configurations described by Pauling and Corey were calculated assuming a perfectly oriented protein fibre with density 1·3 and average residue weight 115. The contribution of the side-chains was neglected, although the C—C bond between the α and β carbon atoms was included. In view of the approximate nature of the calculation the use of co-ordinates for compound α-helices[8] was not justified. The method of calculation, due to Bunn, has been described by Seeds[9]; it is of limited application, however, as the values of the C=O and C—N bond polarizabilities used do not refer to the peptide linkage.

It would appear from the initial birefringence values observed in hair (c. 0·007) that a significant fraction of the keratin must be poorly oriented. This conclusion is supported by the low dichroism of the N—H modes observed by Ambrose and Elliott in the infra-red spectra of hairs[3,10], and the electron micrographs obtained by Mercer and Rees[11]. The increase in birefringence on extension is probably due, therefore, to the co-operation of crystalline fibrillar and amorphous matrix components. The increase of anisotropy

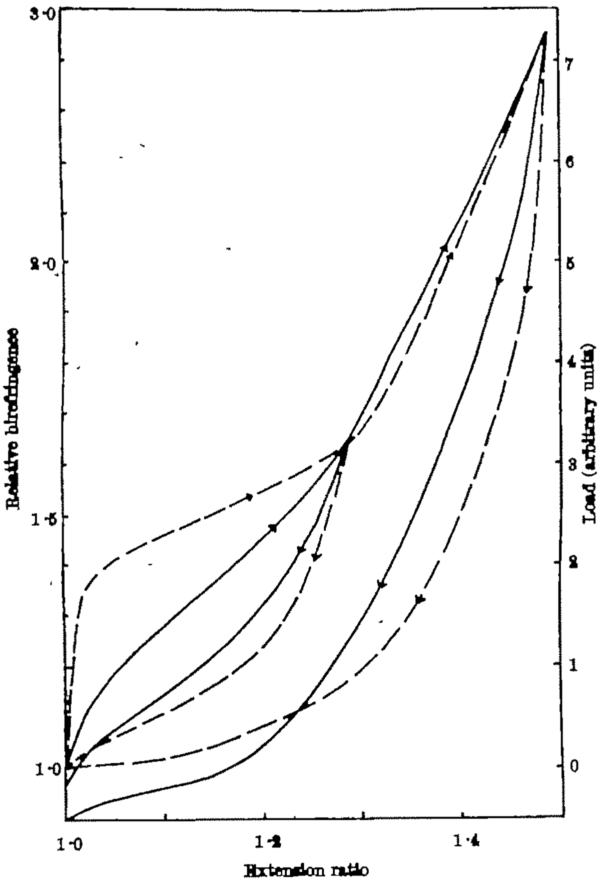

Fig. 1. Average values of birefringence (full curves) and load (broken curves) for about 30 per cent and 50 per cent human hair

in the matrix would be expected to contribute a small, approximately linear increase in birefringence with extension, as observed in rubber[11], for extension ratios up to 1·5.

An examination of the theoretical form of the birefringence/extension relationship for a number of idealized systems, including rubber-like behaviour[12] and crystallite orientation[13], reveals that all are approximately linear in the observed range of extension ratios. A pronounced change in slope may be considered, therefore, to involve a transition from one idealized behaviour to another. A process of disordering, for example, crystalline → amorphous, or cross-linked → free chains, will lead to a decrease in slope and vice versa.

From the high initial slope of the birefringence/extension curve we may suppose that an improvement in orientation or development of strain in the crystalline regions of the fibre is involved. In the range of extension ratios c. 1·02–1·20 a progressive reduction in slope indicates a transition to a less ordered system, probably involving a destruction of the crystallinity. This observation is in accord with the thermodynamic data of Bull[14] and Woods[15], who showed that the contribution of the entropy term to the stress in this range is negative, that is, the increasing entropy assists the extension process, and is also supported by the observation that progressive swelling of the hair occurs[16]. Further support is obtained from the hysteresis upon contraction, which is the reverse of that observed in rubber[11]. In hair there is a persistence of disorder leading to a lower value of birefringence on the return cycle.

At higher extension ratios the slope increases and becomes approximately linear, indicating a resumption of ordering upon extension with consequent decrease in entropy. This may be correlated with the positive contribution of the entropy term to the stress in this region[14,15]. The persistence of similar hysteresis implies that the destruction of crystallinity is not yet complete and the newly formed order decays rapidly.

The determination of each birefringence/extension curve took about an hour. It has been noted that birefringence decays slowly if the hair is held extended, and the hysteresis loop is diminished by rapid extension. The values of birefringence are not, therefore, either instantaneous or equilibrium values; but it is unlikely that this will affect the general conclusions drawn from the experiments.

From an isolated observation, Nutting *et al.* reported a 20 per cent increase in the birefringence of horse hair at 70 per cent extension[17]; in the present experiments a 150 per cent increase at 50 per cent extension was commonly observed. The large discrepancy may be due to a rapid relaxation of birefringence at high extensions in their measurements.

Occurrence and Endodermal Origin of the Peritrophic Membrane in some Insects

The literature[1] on the occurrence, method of formation and function of the peritrophic membrane encircling the food in the midgut of many insects is extensive and contradictory. This is partly due to the lack of satisfactory criteria of what constitutes this membrane (the presence of chitin is the only commonly recognized feature) and partly to a rather widely held belief that the endodermal midgut is unable to produce a chitinous membrane.

Two different types of membrane are held to occur. One type arises from a ring of cells at the anterior end of the midgut which have been reported to be ectodermal in origin[2]. The second type is believed to arise by delamination from the surface of the general midgut epithelium, although this view is not universal. The membranes (of the second type at least) possess a fibrillar 'fish-net' structure, generally with less well-organized material overlying the net and filling the interstices[3]. The peritrophic membrane is thought to protect the midgut epithelium from damage by hard or sharp particles of food, and it is often stated to be lacking in most fluid-feeding insects.

By the use of a small glass boat contained in a miniature stainless-steel pressure vessel, the van Wisselingh test for chitin[4] has been applied both to highly organized and to more fragmentary membranes. Using a positive test for chitin as the criterion, a peritrophic membrane has been found to occur in many insects where it is generally believed to be absent, for example, in many adult Lepidoptera, in many adult Nematocera and Orthorrhapha (Diptera), in larval Dermestidae and adult Carabidae (Coleoptera), in some adult ants (Hymenoptera) and in *Gryllotalpa* (Orthoptera). A peritrophic membrane has also been reported from Corixidae[5] (Hemiptera). The generalization that fluid-feeding forms lack a peritrophic membrane must now be modified. Furthermore, it is clear that a peritrophic membrane is possessed by many insects which have no occasion to protect their midgut epithelium against hard particles of food.

As reported by several previous authors[6], mosquitoes and many other blood-sucking Diptera form a chitinous membrane around the blood meal in the enlarged posterior midgut. If a second blood meal is taken before the first is digested, the new blood surrounds the first meal and a second chitinous membrane is, in turn, secreted around the entire mass. Since the anterior midgut is of much smaller diameter than the posterior midgut, the chitinous membrane must have been formed *in situ* in the latter region either as a result of delamination from the cell surface or of secretion of a fluid precursor which condenses around the food. This evidence clearly indicates that the endodermal midgut epithelium is capable of producing a chitinous membrane, and there is good evidence that this process also occurs in many other insects. The embryonic origin of the cells at the anterior end of the midgut which secrete the first type of membrane now requires re-examination, for it would be surprising if the loss by the endodermal midgut of the capacity to secrete a peritrophic membrane were so frequently accompanied by the assumption of this function by cells derived from the ectodermal foregut, particularly where one type occurs in the larva and the other type in the adult of the same species (for example, Culicidae, Tabanidae).

Since the peritrophic membrane is formed at the surface of midgut cells carrying a striated border it is an attractive theory[3] that the 'holes' in the nets correspond with the spaces occupied by the rodlets of this border during the formation and orientation of the fibrils constituting the nets.

The capacity to produce a delaminated chitinous peritrophic membrane appears to have been an attribute of ancestral insects, since primitive insects (Collembola, Thysanura) possess this capacity as also do other representative arthropods (*Peripatus* (Onycophora), some Chilopoda (Myriapoda), Cladocera (Crustacea)).

Further details of these investigations are in the press[7].

Leucine - Isoleucine Content of Wool

THE procedure described by Moore and Stein[1] for the chromatography of protein hydrolysates on columns of 'Dowex 50' permits a complete separation and estimation of leucine and isoleucine. This has not previously been possible with the methods of quantitative analysis which have been applied to wool. Martin and Synge[2], using a commercial merino 64's quality dry-combed top, prepared a leucine fraction from the acetylated hydrolysate by counter-current extraction. They compared the optical rotation of this fraction with the rotations calculated for pure acetyl-L-leucine and acetyl-L-isoleucine, and estimated the total amount of leucine isomers present to be 7·2 per cent (leucine nitrogen as per cent total nitrogen) and the ratio of leucine to isoleucine to be approximately 4 : 1. Graham, Waitkoff and Hier[3] employed the microbiological method of Hier, Graham, Freides and Klein[4] to analyse an unspecified grade of wool and found the leucine isomers present to account for 8·3 per cent of the total nitrogen, with a ratio of leucine to isoleucine of 1·8 : 1. The figures quoted by these workers for the fourteen amino-acids which they determined are, in general, higher than those reported elsewhere (for example, Speakman[5]).

In the course of a total amino-acid analysis of 64's quality merino wool recently carried out in this laboratory, using the procedure of Moore and Stein[1], we have been able to separate completely and estimate the proportions of leucine and isoleucine present. The mean and standard error obtained from eight replicate analyses for each of these amino-acids are as follow :

Leucine	4·90 ± 0·12 per cent
Isoleucine	1·97 ± 0·05 ,, ,,
Total leucine isomers	6·87 ± 0·17 ,, ,,
Ratio of leucine to isoleucine	2·48 : 1

The total amount of leucine isomers present is therefore close to the figures recorded by Martin and Synge[2,6], but not to those quoted by Gordon, Martin and Synge[7]. The ratio of leucine to isoleucine differs considerably from those previously reported.

I wish to express my thanks to Mrs. H. M. Forss for technical assistance, and to Mr. W. B. Hall for help with the statistical analysis of the results.

A full account of this work will be published in due course.

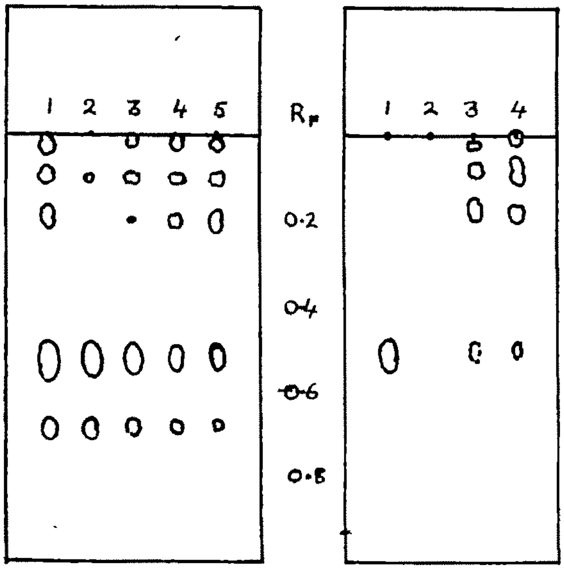
Chlorogenic Acid and the Enzymic Browning of Apples and Pears

Joslyn and Ponting[1] have recently stressed the meagreness of the information regarding individual phenolic compounds involved in the enzymic browning of fruits, although they suggested that chlorogenic acid was a possible substrate (cf. Ingraham and Corse[2]). Since chlorogenic acid is known to be acted on by the polyphenoloxidase of sweet potatoes[3], and to be widely distributed in many plant tissues including apples and pears[4], we have investigated its role in the enzymic browning of these two fruits.

Paper chromatograms run in butanol – acetic acid – water (4 : 1 : 5) of crude concentrated acetone extracts of Bramley's seedling apples show the presence of five fluorescent components when viewed in ultra-violet light in the presence of ammonia, three of which (R_F 0·02, 0·08 and 0·20) show only faintly (Fig. 1). The major compound (R_F 0·54) was separated by large-scale paper chromatography and shown to be chlorogenic acid by identity of R_F values in several solvents, colour reactions[5], and ultra-violet absorption spectra in ethanol and 0·002 *M* sodium ethoxide solution[6].



(*a*)
(1) Crude acetate extract of apple tissue; (2)–(5) chromatograms of apple during course of browning

(*b*)
(1) Chlorogenic acid; (2) apple enzyme extract; (3) mixture of (1) and (2) after reaction; (4) mixture of (1) and pear enzyme extract after reaction

When samples of the tissue are minced in phosphate buffer *p*H 6·7 and air is bubbled through the suspension, a rapid browning takes place. Chromatograms of the extract show that as browning proceeds the intensity of the compounds of low R_F value increases and that of chlorogenic acid and the other component decreases (Fig. 1,*a*). Tissues minced in the presence of ascorbic acid or thiourea in which no browning takes place show the presence of chlorogenic acid and the faster running component only.

Tests were carried out in phosphate buffer with pure chlorogenic acid plus either a suspension of minced tissue which had been pre-washed with acetone at – 20° C. until free of phenols, or the polyphenoloxidase extracted from it with 1 per cent sodium carbonate solution[7]. In both cases passage of air through the mixture gave rapid browning. Chromatograms of the mixture showed that the three compounds of low R_F values found above were produced during the course of the reaction (Fig. 1,*b*). When catechol was used as a substrate, no formation of the three slow-moving components was found, although strong browning was observed.

Similar results have been obtained with chlorogenic acid and an enzymic preparation from Conference pears. Thus it is apparent that chlorogenic acid is one of the substrates involved in the enzymic browning in both apple and pear, and that the three fluorescent compounds (R_F 0·02–0·20) are formed from it during the reaction.

Glycogen in the Dividing Cells of the Liver of the Chicken Embryo

VON GROPP[1] has investigated the distribution of glycogen in hepatic cells of the rat after the administration of the carcinogen butter yellow (*p*-dimethylaminoazobenzol). Using Best's carmine technique and the periodic acid–Schiff sequence, he concluded that the amount of glycogen in dividing cells was considerably less than in non-dividing cells. It was further found that when individual dividing cells were examined glycogen was found in 84 of 200 cells (42 per cent), whereas it was present in nearly all the non-dividing cells. The same difference in the glycogen content of dividing and non-dividing cells has been recorded in a transplantable tumour of the rat liver by Strong and Smith[2]. This note records the results of equivalent investigations on the liver of the chicken embryo.

Glycogen can be demonstrated histologically in the liver of the chicken embryo at the end of the seventh day of incubation[3]. In the present investigations the liver was removed from the embryo during the eighth and ninth days and immediately fixed in Carnoy's fluid. Sections were stained for glycogen by the periodic acid – Schiff sequence, as described

Table 1. GLYCOGEN IN HEPATIC CELLS

Type of liver	Dividing cells		Non-dividing cells	
	Number examined	Per cent positive	Number examined	Per cent positive
Embryonic chick (8th day of incubation)	80	71	78	76
Embryonic chick (9th day of incubation)	91	80	82	71
Embryonic chick (9th day of incubation)	62	89	56	84
Adult rat treated with butter yellow (von Gropp[1])	200	42		nearly all

by Lillie[4], using control slides treated with saliva. Glycogen was found in the majority of non-dividing hepatic cells, mostly as 1–4 clumps about 2 μ in the longest diameter. In other cells it was in the form of fine granules and in some cases these granules were scanty. In the dividing cells, glycogen was found to have a similar distribution, and no difference could be detected in the glycogen content of dividing and non-dividing cells. To reinforce this subjective assessment the presence or absence of glycogen was determined in individual cells.

Sections were examined at a magnification of × 750. Whenever hepatic cells in division were observed the presence or absence of glycogen was determined in these cells as well as in a non-dividing hepatic cell selected at random in the same field. The results for three embryonic livers are recorded in the table. In all three cases it was found that more than 70 per cent of dividing cells contained glycogen, which is significantly greater than the 42 per cent recorded by von Gropp[1] in the rat liver after treatment with butter yellow. Furthermore, in the embryonic liver there is no significant difference in the proportion of dividing and non-dividing cells which contain glycogen. Thus the diminished glycogen content found in the dividing cells of the rat liver treated with a carcinogen[1] and also in a hepatic tumour[3] has not been found in the liver of the chicken embryo. This difference may be of importance since, in the liver, similarities have been suggested in neoplastic and embryonic tissue[5].

Inhibitory Action of Cocaine

DURING a study of the inhibitory action of cocaine on cellular respiration, we found that the oxidations of added pyruvate by brain homogenate and by the respiring yeast, *Torulopsis utilis*, were inhibited to a similar degree, a 0·002-*M* concentration of the drug causing an inhibition of about 50 per cent in each case. It had previously been shown, using *Saccharomyces cerevisiae*, that the inhibition of fermentation by cocaine could also be attributed to the blocking of pyruvate metabolism, carboxylase being inhibited[1,2].

Further analysis with the view of discovering more precisely the site of respiratory inhibition gave results, details of which will be published elsewhere, which, when considered in conjunction with pharmacological evidence (anti-acetylcholine effect), suggested that cocaine interfered either with the activation of acetate or with the utilization of active acetyl groups. One line of investigation to test this theory was to study the effect of cocaine on the biosynthesis of citrate from acetate.

In experiments with yeast we followed the procedure of Weinhause and Millington[3], whereby citrate accumulates in an aerated suspension of starved bakers' yeast in 0·2 *M* magnesium acetate; the further metabolism of citrate being prevented by the magnesium inhibition of aconitase. Mixtures having an initial *p*H of 7, with and without cocaine, were aerated at 30°. Samples were withdrawn at intervals for the estimation of citrate by the method of Natelson, Pincus and Lugovoy[4].

In a typical experiment the following results were obtained:

	Time (hr.)	Citrate, μgm. per ml. yeast suspension	
		No cocaine	Cocaine, 0·001 *M*
a	0	38	38
b	1*	98	79
c	3	319	150
Synthesis during 2 hr. (*c* − *b*)		221	71

* The *p*H of the mixtures, determined electrometrically, was readjusted to 7 by addition of acetic acid.

In this experiment, during the two-hour period which falls in the most active stage of citrate synthesis, cocaine (0·001 *M*) inhibits the accumulation of citrate by 68 per cent.

Our results show that the toxicity of cocaine towards tissue respiration lies in the ability of the drug to block the entry of two-carbon fragments into the tricarboxylic acid cycle, either by a specific inhibition of the condensing enzyme or by preventing the formation of available active acetyl groups. The latter possibility is being further investigated.

Hydrolysis of Esters by Extracts of Insects

O'BRIEN, in a recent communication[1], said that our remarks in the two publications to which he refers[2,3] could be interpreted as a statement that there was no choline esterase in adult *Tribolium castaneum* Hbst. or larvæ of *Tenebrio molitor* L. The relevant sentences (ref. 3, p. 496) are as follows: "Preliminary tests with preparations of whole *Tribolium castaneum* Hbst. and *Tenebrio molitor* L. failed to show any activity in hydrolysing acetyl choline. It should be pointed out that no persistent attempt was made to prepare an extract hydrolysing acetyl choline since these preparations were found to have considerable esterase activity in hydrolysing ethyl butyrate and *o*-nitrophenyl acetate. It is possible that with a different technique these insects may prove a satisfactory source of choline esterase".

O'Brien states that our paper led Hopf[4] to believe that there was no choline esterase in adult *T. castaneum* and larvæ of *T. molitor*, but careful consideration of the paper shows that he interpreted our work to mean that esterases other than those which hydrolyse acetyl choline may be important in the insecticidal action of organo-phosphorus compounds, and indeed attached no theoretical importance to our inability to demonstrate the hydrolysis of acetyl choline in extracts of *T. molitor* and *T. castaneum* with the techniques which were then available to us. O'Brien further inferred that our publications indicated that we had used a percentage of alcohol in these preliminary tests, which is known to inhibit choline esterase activity, and had centrifuged the extracts and rejected the solids. No alcohol was used in the preliminary tests for choline esterase activity nor were the extracts centrifuged. The preparation to which he refers was used exclusively in the study of the inhibition of the esterases hydrolysing ethyl butyrate and *o*-nitrophenyl acetate, which are stable and soluble in the presence of a high percentage of alcohol.

We consider that the figures given by O'Brien for extracts of whole *Tribolium confusum* adults cannot be accepted as proof of similar activity in *T. castaneum* adults. Further, his figures for activity in both *T. confusum* adults and *T. molitor* larvæ are comparatively low and their significance is difficult to assess in the absence of the blank, which may be large (see Table 1). We ourselves have since been able to demonstrate hydrolysis of acetyl choline by extracts of parts of adult *T. castaneum* but not of the whole insects, or by whole *T. molitor* larvæ (see Tables 1 and 2). We believe that it is likely that enzymes hydrolysing acetyl choline also occur in the larvæ of *T. molitor*, although so far we have not been able to demonstrate them.

The main point of our communications was that, in insects, the study of the effect of organo-phosphorus compounds on esterases should not be limited to those hydrolysing acetyl choline; we did not wish to imply that we considered choline esterase activity unimportant. In fact, as part of a study of the anti-esterase activity of organo-phosphorus insecticides, we have been investigating the choline esterase activity of extracts prepared from a number of species and instars of insects.

Table 1. HYDROLYSIS OF ESTERS BY EXTRACTS OF WHOLE INSECTS

* Extracts were prepared in all cases by homogenizing with ice-cold water in an all-glass apparatus.

The use of crude extracts prepared by grinding whole insects with ice-cold water does not always yield preparations suitable for the measurement of the hydrolysis of acetyl choline by the Warburg technique. Our experimental technique was as follows. The insects were homogenized in ice-cold water and the activity was determined using the standard Warburg technique. The main vessel contained 0·5 ml. of 1 per cent sodium bicarbonate, an aliquot of extract, distilled water to make the total volume of fluid in the vessel to 3 ml.; 0·3 ml. of 0·5 per cent acetyl choline chloride was placed in the side bulb. The manometers were gassed with a mixture of 95 per cent nitrogen, 5 per cent carbon dioxide, and all determinations were carried out at 25° C.

In many cases a comparatively large amount of acid production occurs in the absence of added substrate, which may obscure the measurement of the hydrolysis of acetyl choline. Table 1 gives some comparative data on the hydrolysis of acetyl choline and phenyl acetate by crude insect extracts, and the rate of acid production in the absence of added substrate at the higher concentrations (usually of the order of 1 ml. of 20 per cent extract per manometer) required to observe the hydrolysis of acetyl choline. We do not have complete data on measurements of the rate of hydrolysis of phenyl acetate by this technique; but using other techniques we have readily demonstrated the hydrolysis of phenolic esters by all species tested. This includes all the species listed in Table 1. The ubiquity of the occurrence of this general esterase activity and its inhibition by organo-phosphorus insecticides suggest that it may be of importance in the action of these substances. This is supported by the apparent absence of choline esterase in the early stages of the eggs of tomato moth, which, as mentioned in our previous publications, can be killed in an early stage of development by concentrated tetraethyl pyrophosphate.

We must point out, however, that inability to demonstrate the hydrolysis of acetyl choline by crude extracts prepared under the mildest of conditions cannot be taken to indicate the absence of enzymes which hydrolyse acetyl choline, as is shown by extracts of *Tribolium castaneum* adults. The results appear to indicate the presence of an inhibitor in the extracts. In *T. castaneum* adults this appears to be largely in the abdomen of the insect, since choline esterase activity could be demonstrated in the head, and head and thorax alone and not in the whole insect. Activity in the whole insect could be shown by dialysis, or by centrifugation, when choline-esterase activity is in the solids. The supernatant partially inhibits the activity of the enzyme in the solids (Table 2). The inhibitor is apparently heat stable, since boiling the supernatant does not destroy it. It is possible that an inhibitor also occurs in *D. fasciatus*, since there is no apparent choline esterase in whole crude extracts (see Table 1), but on dialysis the hydrolysis of acetyl choline may be observed, and in 30 min. 1 gm. of insects liberates 80 c.mm. of carbon dioxide in the absence of added substrate and 160 c.mm. in the presence of acetyl choline.

Schottky Defects in Solid Solutions

IN the various statistical thermodynamic treatments of substitutional solid solutions, it is tacitly assumed that the number of unoccupied lattice sites in the solution is either zero or the same as the number in the separated components. This assumption seems unsatisfactory on general grounds, and is, in fact, not supported by experiment. The nickel–aluminium system is in this respect a spectacular case, since at some compositions in the β-phase vacancies occur[1] in excess of 5 per cent. This system is, however, atypical in that, among other things, the vacancies seem to originate in special electronic effects, since the fraction of unoccupied sites varies with composition in such a way that the number of conduction electrons per unit cell is maintained constant. Schottky defects in alkali halide solid solutions have a simpler origin. The distribution over a group of lattice sites of two or more ions differing appreciably in size introduces stresses which lead to local lattice distortions and the occasional ejection of an ion.

In solid solutions of potassium and sodium chlorides, a maximum of 1·1 per cent Schottky defects was observed[2] for a solution in which the mole fraction of sodium chloride was 0·699. Thus in the solid solution vacancies are a hundredfold more abundant than in the pure salts. In solid solutions of potassium and sodium chlorides, the size difference is large and one expects extensive vacancies. It is of interest to note that vacancies are even more abundant in the potassium chloride and bromide system where the percentage difference in ion size is only one-fifth as large. The data are given in Table 1, where the measured densities are by Tammann and Krings[3] and the calculated results are from the unit cell dimensions reported by Oberlies[4]. Errors assigned to the densities were established by comparing the data on the pure salts either with other literature results or with quantities determined in this laboratory. The errors assigned exceed by at least a factor of 10 the precision claimed in the original publications. For the two cases cited, Schottky defects in the solid solutions are orders of magnitude more abundant than in the separate salts, and from general considerations it seems likely that this is the usual situation with most solid solutions.

Table 1. DENSITIES AND SCHOTTKY DEFECTS IN SOLID SOLUTIONS OF POTASSIUM CHLORIDE AND BROMIDE AT 25° C.

Mole % KCl	Density (gm./cm.³)		% Schottky defects

100	1·994 ± 0·006	1·994 ± 0·006	—

All the binary alkali halide systems which have been studied[2,5–7] are endothermal with respect to their components, and the curve showing the heats of solid solution versus composition rises more steeply on the side of the component of smaller lattice constant than on the opposite end of the composition scale. This and a similar asymmetry in the solid-solution demixing curve[2,8] show clearly the expected behaviour, namely, that stresses are more acute when replacing a small ion with a large one than for the reverse process. Thus one is led logically to the notion that Schottky defects will be more extensive in the solutions which are richer in the smaller substituting ion. Not only is this trend apparent in the two salt systems cited but also it is followed[9] in the metallic system magnesium–cadmium, where geometrical factors are important (in this case shape difference rather than size difference is probably more important). Elsewhere it has been pointed out that the cadmium-rich solutions possess vacancies up to 2 per cent. Unpublished calculations indicate an undetectable percentage of vacancies in the magnesium-rich solutions. An interesting feature of this system is that the $MgCd_3$ superlattice contains 1·7 per cent Schottky defects which remain frozen-in at absolute zero and produce[10] a substantial departure from the third law of thermodynamics.

The existence of extensive vacancies in the system sodium–potassium chloride has received recent indirect confirmation by Hyvonen[11] and by Scheil and Stadelmaier[12] in studies of the kinetics of precipitation in it. In both investigations an activation energy at low temperatures of about 20 kcal. is found, which is close to the value required to move a vacancy[13]. If the vacancy must be formed and moved, an activation energy of approximately 60 kcal. is needed[13].

The foregoing remarks raise some interesting questions regarding recent and apparently successful attempts to calculate the energies of alkali halide solid solutions. Earlier efforts were unsuccessful because of failure to allow for lattice distortions. Wasastjerna[14] and Durham and Hawkins[15] have taken into account the energy reductions resulting from lattice distortions, and Wasastjerna in addition has evaluated the local-order parameter and made allowance for the reduction in energy due to departures from a random distribution. Both treatments were remarkably successful in accounting for the energies associated with the formation of potassium chloride–bromide solutions without allowing for the observed number of empty sites. If one can judge from the energy required to create a vacancy in a pure salt, the energy difference between a sound potassium chloride–bromide lattice and one containing of the order of 1 per cent defects should be considerable. It therefore seems that the success of these theories is largely fortuitous.

This work was assisted in part by the U.S. Atomic Energy Commission.

Low-Frequency Noise in the Range 0·5-20 cycles per sec.

IN order to further understanding of magnetic fluctuations in the frequency range 0·5–20 cycles per sec., a programme was initiated by the Geophysics Research Directorate, U.S. Air Force Cambridge Research Center, in November 1949. The work done by Menzel and Salisbury[1] and by Willis[2] was continued with the view of obtaining correlation with other geophysical and solar phenomena.

The apparatus consists of a pick-up loop with an effective area of 257 sq. m., a battery-operated A.C. amplifier designed for flat response from 0·5 to 20 c./s. and a gain of 160 db., and a recorder originally made for seismographic work. The recorder, designed by R. L. Blumberg, has galvanometers flat to 40 cycles; chart speed is 1 mm. per sec.

The equipment is at Maynard, Massachusetts, in a concrete building made for ammunition storage. The loop, located approximately 150 ft. from the building, and the connecting cable are buried approximately one foot deep. A second site is located in the desert of New Mexico. Both sites are remote from power lines and were chosen for their low-noise characteristics.

Calibration of the amplifiers took place at least three times weekly. Fig. 1 illustrates the records obtained for a noise storm, a quiet period, and for calibration voltages.

Continuous recordings were maintained, and readings made hourly. An index for low-frequency noise was formulated by measuring the width of the base-level and reducing the readings to a uniform calibration of 10 mm. = 1·0 μV. Spike activity unaccompanied by an increase in base-level was usually transient. An index for solar radio noise (200 Mc./s.) was formulated in the same manner.

The existence of storms in the frequency-range under consideration seems indisputable. During some intervals of heavy activity, values of more than a hundred times that of quiet-period readings were recorded. These storms occur quite frequently and cannot be attributed to man-made disturbances. Very often periods of heavy activity were found to coincide with similar periods in other geophysical phenomena[3].

A definite diurnal variation exists in the low-frequency data, and this variation is very much like that of the magnetic K-indices from Cheltenham (Fig. 2). Points are plotted for every three hours. The low-frequency curve represents 350 days of data; the K-index curve represents 450 days.

In an attempt to determine whether or not low-frequency noise is of purely local origin, apparatus was set up at a second site near Alamagordo, New Mexico. Amplification and recording equipment was the same and operating procedures identical at the two sites. The pick-up coils, however, differed in characteristics, the coil at Alamagordo presenting an effective area approximately fourteen times greater than that at Maynard. The noise-level recorded at Alamagordo was considerably lower than that at Maynard. The analysis of the corresponding records has not been intensive; but the following results are indicated. A tentative diurnal variation has been established for Alamagordo from the data of one month and displays characteristics similar to those of the Maynard variation. The second result is a fairly close correspondence in sense, though not in magnitude, of the daily means at the two sites during a stormy period in August 1952. The storm can be divided into three major phases at both sites (Fig. 3).

A correlation and coincidence analysis was undertaken to determine interrelationships between low-frequency noise and other geophysical phenomena. Correlation coefficients of no significance were obtained between low-frequency noise and (1) ionospheric storminess and (2) Cheltenham K-index. Coincidence studies for low-frequency noise and (1) solar flares and (2) SID's revealed no direct relationship. A cross-correlation function was computed for low-frequency noise and solar radio noise (200 Mc./s.). A marked peak (0·57) occurs at $T, = 29$. That is, there is a very significant correlation between what happens one day on solar noise at 200 Mc./s. and what happens on low-frequency noise

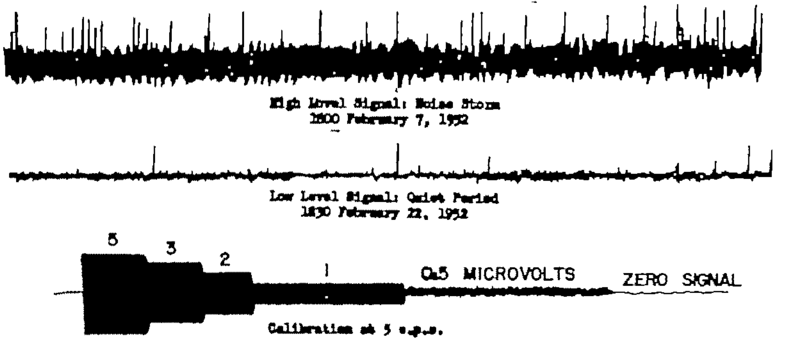

Fig. 1. Examples of various signal and calibration levels

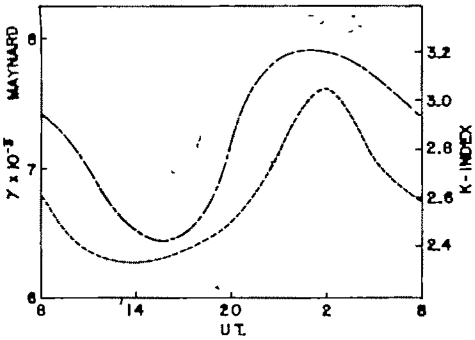

Fig. 2. Diurnal variation of low-frequency noise (......) and magnetic K-index (— · — · —)

twenty-nine days later (Fig. 4). A tentative auto-correlation function was computed for the low-frequency data in case any internal cyclic tendency had escaped notice. There is a peak (0·44) at $T = 37$ days.

From the calculations made thus far, it would seem that the phenomenon under investigation is a real, non-spurious, low-frequency disturbance, and that this disturbance has a regular diurnal variation. In addition, several tentative results seem indicated. The disturbance would not seem to be entirely local in origin; the base-level activity in the low-frequency range resembles to some degree that of solar noise at 200 Mc./s. as recorded twenty-nine days earlier; and the diurnal variation of the low-frequency noise resembles that of magnetic K-indices. It is, of course, noteworthy that the lag between solar radio noise and low-frequency noise is within the range of the solar rotational period.

Control of *Pseudomonas syringae* with Streptomycin

GLASSHOUSE experiments on the control of stone-fruit-blast (*Pseudomonas syringae* van Hall), a serious disease of stone-fruit trees in New Zealand, have recently been carried out using twenty-three proprietary therapeutants and five antibiotic substances at varying concentrations. Vigorously growing seedling peach trees (*Prunus persica* Sieb. and Zucc.) were used as test plants. With a sterile needle stems were lightly pricked at fifteen points and then sprayed with treatment solutions. After 1½ hr., by which time all plants were dry, they were sprayed with a 48-hr. beef-peptone-broth culture of a highly pathogenic strain of *Ps. syringae* and placed for three days in a cabinet at 12° ± 2° C. and approximately 90 per cent relative humidity. Since plants kept for a longer period in this cabinet regularly dropped their leaves, they were removed after three days and placed for seven days in a humidity cabinet where the temperature was 16° ± 6° C. and a water mist was automatically distributed for 35 sec. every 3½ hr. At the end of the ten days, number and length of lesions were recorded. Treatments were repeated on four different dates. By using the above technique a consistently high infection-rate was obtained, lesions developing at more than 85 per cent of damage points on check plants.

Materials used were as follow:

Bordeaux mixture (copper sulphate, hydrated lime, water)
'Copox' (copper oxychloride)
'Perenox' (cuprous oxide)
'Taline' (colloidal copper)
'Venturicide' (phenyl mercury chloride)
'Ascospray' (phenyl mercury chloride)
'Thirospray' (tetramethyl thiuram disulphide)
'Fernasan B' (tetramethyl thiuram disulphide)
'Fermspray' (ferric dimethyl dithiocarbamate)
'Phygon XL' (2,3-dichloro-1 4-naphthoquinone)
'S.R.406' (n trichloromethylthiotetrahydrophthalimine)
'Murfixtan' (phenyl mercury salt of naphthyl methane sulphonic acid)
'Crag 658' (copper zinc chromate)
'Crag 5379' (1,2,3-trithio 5,8-diazacyclononane-4,9-dithione)
'Crag 5400' (α α trithiobis (N dimethylthioformamide))
'Manzate' (manganese ethylene bisdithiocarbamate)
'Dithane Z78' (zinc ethylene bisdithiocarbamate),
'Tetroc' (tetrachloro p-benzoquinone)
'Zirospray' (zinc dimethyl dithiocarbamate)
8-Quinolinol
8-Quinolinolate benzoate
Zinc 8-quinolinolate
Copper 8-quinolinolate
Streptomycin sulphate, 725 units per mgm.
Aureomycin hydrochloride, 550 μgm. per mgm.
Crude terramycin hydrochloride, 490 μgm. per mgm.
Chloromycetin, 750 μgm. per mgm.
Crystalline patulin

None of the proprietary therapeutants was highly effective under these conditions, the best being 'S.R.406'. Used at concentrations of 2 lb., 3 lb. and 4 lb. per 100 gallons water, lesions developed at 53 per cent, 60 per cent and 80 per cent of the inoculation points compared with 88 per cent, 93 per cent and 89 per cent respectively on check plants sprayed with water. At the highest concentration, 'S.R.406' caused considerable foliage damage. Of the antibiotic materials tested, streptomycin sulphate was outstandingly the best. On plants sprayed with streptomycin at concentrations of 250, 500 and 1,000 μgm. per ml., lesions occurred at only 16 per cent, 12 per cent and 10 per cent of the sixty inoculation points, compared with 87 per cent, 88 per cent and 93 per cent respectively on check plants. Streptomycin sulphate caused no damage at any concentration used. The average lesion-length on check plants was 3·1 mm. compared with 2·3 mm. and 1·3 mm. respectively on plants sprayed with streptomycin at 500 and 1,000 μgm. per ml. Aureomycin, while substantially reducing infection at 1,000 μgm. per ml. (20 per cent infection), was ineffectual at 500 μgm. per ml. (87 per cent infection) compared with 93 per cent and 100 per cent infection respectively on check plants.

It is particularly noteworthy that streptomycin sulphate has been effective when other materials accepted as therapeutants have not controlled the stone-fruit-blast bacterium. It is also of interest that several therapeutants gave less control at high concentrations than at low concentrations.

Further field and glasshouse experiments are in progress and will be reported elsewhere. I wish to thank Mr. M. H. Dye, Microbiology Section of this Division, for suggesting the use of, and for technical advice on, the antibiotic materials used.

Effect of Antibiotics on the Growth of the Silkworm, *Bombyx mori* L.

ORAL administration of antibiotics such as penicillin, streptomycin, aureomycin and chloromycetin is known to stimulate the growth of mammals[1] and birds[2]. So far, no analogous work appears to have been carried out with insects.

The beneficial action of the antibiotics has been attributed (*a*) to their activity in conditioning the composition of the intestinal flora[3], (*b*) to their potential role as possible growth-factors for the host[4], and (*c*) to their ability to increase, in some yet undiscovered manner, the biological efficiency of the animal as a converter of feed into body-weight[5].

Our earlier experiments with antibiotics were concerned with a study of their effect on the incidence of disease among batches of silkworm larvæ when they were fed with supplements of protein hydrolysates. They showed that penicillin and streptomycin bring about a significant increase in the body-weight of the larvæ when administered along with protein hydrolysates[6]. This work has now been extended to other antibiotics—aureomycin, terramycin and chloromycetin. Since these antibiotics have been known to influence the utilization of proteins by animals, extra supplements of nitrogen in the form of two types of amino-acid mixtures, corresponding in composition respectively to that of casein and silk fibroin, were also supplied to the larvæ treated with the antibiotics. Necessary control batches without the antibiotic and the supplements were maintained simultaneously.

The 'silk mixture' consisted of only the four major amino-acids of the silk fibroin, namely, glycine, alanine, serine and tyrosine, in approximately the proportion in which they are known to occur in the protein. The Mysore × C. Nichi-1 cross-breed larvæ after the third moult were selected for equal weight and size. Batches of ten larvæ were assigned in duplicate for each treatment, and each of the individual larvæ was reared separately in a glass cage of its own and fed by the 'sandwich' technique developed by us[7]. The maximum average weight attained by the larvæ, the average weight of the pupæ and that of the silk are given in the accompanying table.

The results show that, of the antibiotics tried, aureomycin and chloromycetin, when administered alone to the silkworm, give an increase of 9–10 per cent both in the body- and the pupal-weights. The output of silk, on the other hand, does not show a corresponding increase; on the contrary, there is a definite decrease of about 5–8 per cent. The amino-acid mixture corresponding in composition to casein, when administered alone, increases the body-weight by about 15 per cent, while the pupal-weight is raised by about 8·5 per cent. The increase in the output of silk is only 2·5 per cent.

When the antibiotics and the amino-acid mixture are given to the silkworm larvæ in combination, the maximum increase of larval- and pupal-weights attained earlier are not only maintained, but also there is a definite 8–14 per cent increase in the output of silk. A similar increase can be observed in the case of the amino-acid mixture corresponding in composition to that of silk also, although it is not so pronounced.

It would appear that antibiotics, when administered alone, shift the nitrogen metabolism of the silkworm in favour of increasing the body-weight at the expense of the precursors of silk. When, however,

	Average weight of 10 mature larvæ (gm.)			Average weight of 10 moisture-free pupæ (gm.)			Average weight of 10 moisture-free silk-shells (gm.)		
	Water	'Casein mix.' (10 per cent extra N)	'Silk mix.' (10 per cent extra N)	Water	'Casein mix.' (10 per cent extra N)	'Silk mix.' (10 per cent extra N)	Water	'Casein mix.' (10 per cent extra N)	'Silk mix.' (10 per cent extra N)
Mulberry leaf only	24·22	27·93	25·91	2·60	2·80	2·51	1·49	1·53	1·51
" " +aureomycin (25 mgm./kgm.)	26·76	27·89	26·91	2·84	2·60	2·51	1·41	1·70	1·55
" " +terramycin (25 mgm./kgm.)	22·58	24·49	24·66	2·71	2·61	2·52	1·48	1·34	1·50
" " +chloromycetin (50 mgm./kgm.)	26·56	29·15	27·31	2·83	2·79	2·52	1·37	1·61	1·60

an adequate quantity of extra nitrogen of high quality is provided, the precursors of silk are formed, as evidenced by the increased output of silk. This would mean that the antibiotics influence the nitrogen metabolism of the silkworm and achieve a better utilization of even the extra supplements of amino-acids. In the absence of the antibiotics, however, this supplemental source of nitrogen does not appear to be utilized for silk production, as can be seen from the table. The 'casein mixture' alone gives only 2·5 per cent increase in the yield of silk, whereas, with the antibiotics, the yield of silk is increased by 8–14 per cent.

The 'silk mixture' alone, being biologically inadequate in its composition, as compared with the 'casein mixture', shows a smaller increase in the larval growth. In combination with the antibiotics, however, increases of weight ranging from 11 to 12 per cent are obtained. It would appear that antibiotics can effect a better utilization of even a biologically inadequate source of nitrogen present in the feed of the silkworm.

Terramycin, either by itself or in combination with the amino-acid mixtures, does not appear to have any beneficial effect either on larval-growth or on silk-production.

Details of this work will be published elsewhere. Our thanks are due to the Central Silk Board, Government of India, for financial assistance, and to the Director, Indian Institute of Science, for his interest.

Selection of the Oil Palm (*Elaeis guineensis*) in Africa

HITHERTO, work on the selection of the oil palm in Africa has been directed chiefly towards increasing the pericarp content of the fruit, the hereditary behaviour of the relevant factors being comparatively well known as a result of the work carried out by the INEAC in the Belgian Congo. It would appear, however, that the production in weight of bunches has as yet been little improved. In large-scale plantations, blocks planted with seed taken from natural palmeries have, under similar conditions, given bunch-weight yields comparable with those obtained from blocks planted with selected seed. This lack of improvement in production in weight of bunches manifests itself particularly in a very wide variation in the yields of individual palms of the present varieties; indeed, this constitutes one of the main causes of the relatively low yields obtained from such plantations. With the view of reducing this wide variability in individual production, the possibility of eliminating mediocre producers in the nursery before field-planting has been investigated.

The basis of this investigation may be indicated as follows. Instead of considering the annual production or total growth of a palm, or group of palms, in terms of vegetative organs and reproductive organs, which are not strictly comparable, I have suggested that the annual production can be expressed with sufficient accuracy by a single figure, namely, the weight of dry matter in the different organs. This method of expressing the potential annual production is valid if groups of plants of the same age, belonging to the same variety and growing under similar conditions, are compared. Bearing in mind the distribution of the dry matter content between the different organs in young palms not yet in production on one hand, and that of producing palms on the other, it was concluded that, at a given time and under similar conditions, the young plants which produced the greatest quantity of leaf matter (that is, number of leaves × average leaf area) would be those which later would give bunch-weight yields above the average.

On this theoretical basis, investigations were made of producing palms to see if there was any correlation between the quantity of leaf-matter produced and bunch production. Six groups of palms, ranging from four years and less (onset of production) to 4–9 years old were investigated. From the collected results, it appeared (1) that there is a positive correlation ($P = 0{\cdot}02$) between bunch production and the number of leaves and spear leaves present in the crown of the palms during the first two productive years; (2) that this correlation disappears two years after the onset of production; and (3) that among very young palms (four years and less), as well as among young palms not yet in production, there is equally a positive correlation between the surface area of the leaf and the pinnæ on one hand and the number of leaves present in the crown on the other. Thus, taking into account the fact that the fronds and central spear in the crown visible at any given moment correspond to the number of fronds produced during the two previous years, it would appear that there is a marked positive correlation between the bunch production of a group of palms during the first two years of production and the quantity of leaves produced by this group during the two years *before* production started. The fact that in six-year-old and older palms, the crowns of which no longer contain any fronds produced before the onset of fruiting, this correlation no longer exists may be explained by the marked antagonism between the vegetative and fruiting developments.

Consideration of experimental results obtained by Mr. J. D. Ferwerda (agronomist of this Research Department) has led to the conclusion that the number of fronds produced before the onset of fruiting, or the potential production of fronds, is a constant genetical factor in a palm or group of palms. As, further, for a particular group of palms, there is a high positive correlation ($r = +0{\cdot}9$) between the cumulative production of this group over two years and the average total yield during twelve consecutive years, the final conclusion may be drawn that there is a positive correlation between the quantity of fronds produced during a particular period before fruiting begins and the weight of bunches produced in later years. From the same results the conclusion has also been reached that there is a positive correlation between the potential frond production of a group of palms before the onset of fruiting and the average precocity of the palms of the group.

The value of the criterion 'production of fronds during a particular period before the onset of production' having been determined, an easy method, enabling this to be put into practice, was sought. It should be borne in mind that, in large plantations, the number of plants produced per annum may reach several hundred thousand. On this account, an attempt was made to establish a correlation between the quantity of leaves produced during a given period and the height of the plant—in practice, the length of the most fully developed leaf. Actually, the length of the frond is the principal factor determining leaf surface, and, as shown above, this is correlated with bunch production. Observations on this point were made on seven series of nursery palms, 4–12 months old. These established the fact that whereas there is almost no correlation between the quantity of fronds produced during a given period of time and the height of the plants at four months, there is a very marked correlation ($P = 0 \cdot 001$) at twelve months (corresponding to an average height of the plants of ± 130 cm.). A rational selection can thus be carried out in the nursery, based on the existing correlation between the height of the plants at one year old and later production in the plantation, provided all other conditions in the nursery are equal.

From the observations made during this study, some inferences have been drawn regarding the antagonism between the vegetative development and the fruiting of palms. These and the corollaries implied would seem to suggest that this antagonism affects the number of fronds produced, the leaf area of the developing fronds, and the rhythm of development in the growing leaf. The evidence also indicates that the onset of production—mainly the active growth of the first female inflorescences—constitutes the opening of a critical period for the palm and creates a physiological disequilibrium which only completely disappears after two and a half years. The incidence of this physiological condition and the antagonism between fruiting and vegetative development have also thrown new light on the pathological condition known as 'little leaf'. Lastly, the criterion of selection in the nursery proposed here may be used to advantage in the selection and breeding of high-yielding palms, the procedure being essentially based on the hereditary transmission of geno-complexes.

This work will be published in full elsewhere.

Wind-borne Dispersal of Potato-Root Eelworm

Since the potato-root eelworm *Heterodera rostochiensis* Woll. became established in the main potato-growing areas of England, it has been realized that this pest can be transferred from infested to free fields in many ways[1,2].

In Britain some of the main potato-growing areas, heavily infested with potato-root eelworm, are situated on deep, light, easily worked land. Some of these areas, such as the moss lands of south Lancashire, the peat lands of the Isle of Axholme, Lincolnshire, the fens of Kesteven, Lincolnshire, and parts of East Anglia, suffer severely from dust storms under certain climatic conditions. Recently, observations were made to ascertain the extent to which cysts of *H. rostochiensis* can be transported during these dust storms. Strachan and Taylor[3], in 1929, suggested the possibility of cysts being wind-borne; but no conclusive evidence has been obtained from work in Britain. Chitwood[4], in the United States, confirmed that cysts were borne with the wind, as he collected small numbers among detritus blown from an infested field on to the surface of snow covering an adjoining uninfested one. The maximum distance at which cysts were recovered was 935 ft. from the source of infestation.

In order to obtain further information concerning the part played by wind in distribution, three traps were erected in March 1953 at Wroot in the Isle of Axholme, Lincolnshire, at the edge of a field of light sand and peat which was known to blow readily. The eelworm infestation on this field was not heavy —eight viable cysts per 25 gm. The traps were of sheet metal, 15 in. square with a light bolting silk bag attached. These were placed so that the centres of the traps were 1 ft. 1¼ in., 2 ft. 6¼ in., and 3 ft. 11½ in. above ground-level. They faced south-west, the direction of prevailing wind which produces dust storms.

On March 28, 1953, such a storm developed. Most fields within an area of 10 sq. miles were blowing. The maximum wind recorded at a nearby aerodrome, three miles to windward of the traps, was 25 knots from a direction 260° from true north.

The results obtained by examining the three catches of soil are given in Table 1.

Table 1

Height of trap	Weight of soil (gm.)	Volume of soil (c.c.)	Fully viable cysts	Semi-viable cysts*	Non-viable cysts
6 in.–1 ft. 9 in.	20,012	17,798	2,077	1,870	9,598
1 ft. 11 in.–3 ft. 2 in.	3,125	3,860	435	567	2,666
3 ft. 4 in.–4 ft. 7 in.	768	970	103	128	447

* Semi-viable cysts containing less than fifty eggs.

Egg-counts made on five samples of cysts gave an average of 137 eggs and/or larvæ per viable cyst, 55·5 per cent being eggs and 44·5 per cent larvæ.

It would appear, therefore, that under the conditions of March 28, 1953, there was a considerable movement of cysts in blowing soil. The conditions existing were by no means exceptional, it being common to have five or six such windstorms each year. On this one day alone, at least 5,180 viable cysts moved over a front 15 in. wide and 4 ft. 6 in. high. This is equivalent to approximately 1,250,000 cysts over a 100-yd. front to a height of 4 ft. 6 in. Although most of these cysts travelled not more than 18 in. above the ground it is considered that they can be easily wind-borne from field to field, since these areas normally have few hedges or other natural windbreaks, the field boundaries consisting of shallow dykes over which soil passes on the wind without hindrance.

It is suggested, therefore, that in these well-defined areas of blowing soil, the agency of wind in bringing about local distribution of eelworm cysts is of con siderably greater importance than the accepted methods of spread, on implements, seed potatoes, etc.

Siliceous Spicules in the Calcareous Sponge, *Leucandra johnstonii* (Carter)

Specimens of this sponge collected at Calf Sound, Isle of Man, were investigated for spicules, and for their arrangement in the body of the sponge. Six types of spicules were found, ranging from very large tetraradiates and triradiates to long slender and minute rod-like oxea[1]. When the acid test was applied to a slide with dried spicules, all except the long slender oxea dissolved. These oxea are present in large numbers, and are set vertically in a palisade round the osculum.

When mixed spicules are examined with a geological microscope, crossing of the nicols causes five of the spicule types to show up as iridescent bodies (calcite); but the long slender oxea disappear—they are isotropic, and probably composed of colloidal (opaline) silica. A sensitive chemical analysis gave a strongly positive test for silica.

So far as is known, in no other calcareous sponge have siliceous spicules been observed. I should be grateful for more specimens of the sponge in order that a full account can be prepared.

The American Slipper Limpet (*Crepidula fornicata*) in Milford Haven

During a short survey of Milford Haven (July 27–30, 1953) for the purpose of assessing the possibility of reviving the oyster fishery, six American slipper limpets (*Crepidula fornicata*) were found in or near Pennar Gut, the estuary of the Pembroke River. *Crepidula*, a serious pest of oysters, had previously been recorded only from the east and south coasts of Britain[1]. The limpets, varying in length from about 12 to 50 mm., were found during approximately half an hour's examination of the shores uncovered at low water of a good spring tide. Much of the time was devoted to other tasks and undoubtedly more limpets would have been found in an intensive search. The limpets taken comprised four singles and one colony of two. Two of the isolated limpets were covering spawn. It has been suggested[2] that isolated females may be capable of self-fertilization, but this has not been proved experimentally. Since young males are actively motile, the possibility that these apparently isolated females had been fertilized by itinerant males cannot be excluded. The minimum size at which males may become sexually mature is not known, but it is certainly very small, probably less than 10 mm., and such tiny males are easily overlooked on the shore.

Pennar Gut was used in the years following the Second World War for laying up both merchant and naval ships, and is adjacent to Pembroke Dock. There is a ship-breaking yard on the opposite shore near Milford Haven. Evidence has been adduced[1] to show that a major factor in the spread of *Crepidula* has been the movement of laid-up naval and merchant ships, which may remain for several years in infested areas on the east and south coasts of Britain and later be transferred for refitting or breaking-up to other areas. Very frequently, such vessels carry mussels and slipper limpets on their bottoms, and as a result *Mytilicola intestinalis*, the copepod parasite of mussels, and *Crepidula* have reached new areas[1,3]. It is to be anticipated that, when a careful search is made, *Crepidula* will be found in the Firths of Forth and Clyde, at Londonderry, Barrow-in-Furness, and at other ports in South Wales, to all of which laid-up ships have been traced after periods in east and south coast ports.

A Plasmodium in Common Indian Partridges

On routine examination of birds commonly found in the vicinity of Delhi during the winter months, a species of avian malaria parasite was observed in some wild partridges (*Francolinus pondicerianus interpositus* Hartert), a species widely distributed in many parts of India and locally known as 'titar' (Hindi).

Gametocytes and all stages of asexual forms were detectable in the erythrocytes. The parasite appears to resemble *P. polare* first found by Manwell (1935) in a cliff sparrow (*Petrochelidon lunifrons lunifrons* Say).

Infection was invariably found to be low; but it had always been possible to passage the infection to fowls and chicks by blood inoculation from partridges showing infection. This infection was later transmitted from partridge to fowl and from fowl to fowl through *Aedes ægypti*.

It is believed to be the first report on any plasmodial infection in Indian partridges.

The strain is now being maintained in fowls and further studies are in progress.

Suckling Reflex in the Cat

FOR experimental purposes, some new-born kittens had to be reared in the laboratory away from the mother. Difficulties were encountered in inducing the kittens to accept milk administered by means of a glass pipette, until a way of evoking the suckling response was found. It was observed that slight pressure from the pipette applied to the premaxillary part of the palate invariably produced the suckling response which was maintained so long as the kitten was disposed to accept food. The main feature of this response is a slight protrusion of the tongue with side-to-side concavity of the dorsum, which assumes the shape of a shoehorn. The nozzle of the pipette is firmly grasped between the tongue and the premaxillary palate. The upturned margins of the more posterior part of the tongue press against the palate. A closed channel is thus formed within the oral cavity. The protruded tip of the tongue works up and down the side of the pipette in a milking action. Suction is created by alternate depression and elevation of the floor of the oral cavity along with the mandible, while the margins of the tongue and the palate together maintain the closed channel.

It will be noted that the mechanism described above differs from that in the human baby, in that the lips take no part at all in sealing the oral cavity off from the exterior. An oral sphincter of the human type does not exist in carnivores.

A Human Blood-Group Gene Intermediate between *M* and *N*

WHILE many blood-group antigens have, subsequently to their discovery, proved to be divisible into a number of sub-types, the *M* and *N* antigens have shown little tendency to be subdivided. Aberrant *M* and *N* antigens have from time to time been described and attributed to corresponding genes, sometimes characterized as M_1 and N_2, but both of these are extremely rare, with frequencies of the order of 1 in 1,000 in all populations hitherto tested. It was therefore with great surprise that we found examples of an abnormal *M* antigen and also of an abnormal *N* in a single English family. The results of our tests on members of this family are shown in Table 1. The sera used have each been tested with consistent results against very many—in some cases thousands—other red cell samples. The classification of the sera into positive and negative reactors with members of the C. family depends solely on tests on members of that family and on incomplete tests on one other unrelated person. All the tests have been carried out at least in duplicate, and in the case of Mrs. C. and K. C. tests have been done on separate blood samples at intervals of several months.

It will be seen that the red cells of Mrs. C. and P. C. react with all anti-*M* sera, but with only three out of twenty-four rabbit anti-*N* and two out of four human anti-*N* sera, while those of K. C. react with all anti-*N* sera and with all but one of twenty-one rabbit anti-*M*, and all but one of six human anti-*M* sera. The Henshaw and Hunter antigens[1] which form part of the *MNSs* complex were shown to be absent from the red cells of all five persons. The wife and daughter of K. C. were both shown to be of the normal genotype *NsNs*.

Table 1. REACTIONS OF RED CELLS OF C. FAMILY WITH ANTI-M, ANTI-N, ANTI-S AND ANTI-s SERA

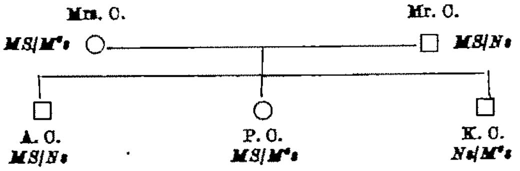
Specificity of sera	Anti-*M*		Anti-*M*		Anti-*N*		Anti-*N*		Anti-*S*	Anti-*s*
Origin of sera	Rabbit		Human		Rabbit		Human		Human	Human
Number of sera	20	1	5	1	3	21	2	2	1	1
Red cells										
Mr. C.	+	+	+	+	+	+	+	+	+	+
Mrs. C.	+	+	+	+	+	−	+	−	+	+
A. C.	+	+	+	+	+	+	+	+	+	+
P. C.	+	+	+	+	+	−	+	−	+	+
K. C.	+	−	+	−	+	+	+	+	−	+

Accepting the stated relationships of the persons tested, the hypothesis of separate M_1 and N_2 genes occurring in the one family is genetically impossible, since K. C. must have obtained his normal *N* from his father and his abnormal *M* from his mother, who however, has a normal *M* and an abnormal *N*. The occurrence of the very rare N_2 and of a mutation from *M* to M_1 in a single family is too highly improbable to be considered.

Samples of the anti-*M* sera which agglutinated the red cells of K. C. were absorbed with normal *M* and *MN* cells and were then found not to agglutinate the K. C. cells. This shows that the agglutination of the cells of K. C. cannot be due to an extra antibody in the anti-*M* sera, corresponding to some rare antigen independent of the *MN* system. It was similarly shown that the agglutination of the cells of Mrs. C. and P. C. was not due to an additional antibody in the anti-*N* sera.

No genetically tenable scheme of modifying genes appears capable of accounting for the phenomena.

The only hypothesis which we have been able to formulate to account for our observations depends on the occurrence of a gene having properties intermediate between those of the *M* and the *N* genes, and allelic to these. If we provisionally call this gene M^c, then it is assumed that red cells of genotype MM^c will be agglutinated by all anti-*M* sera and by some, but not all, anti-*N* sera, whereas those of genotype NM^c will be agglutinated by all anti-*N* sera but only by some anti-*M* sera. The gene M^c, being an allele of *M* and *N*, will be closely linked to *S* or *s*. Sera were fortunately available to test all members of the family with anti-*S* and anti-*s*, and the reactions of the cells of the five persons with each of these two sera provide a critical test of the hypothesis. The reactions of all members of the family can be accounted for in full by assigning them the genotypes shown in the accompanying diagram.



The *MNSs* genotypes of the C. family

The properties here attributed to the M^c gene are almost completely analogous with those of the c^v gene in the *Rh* system[2].

The agglutination experiments were supported by numerous titrations, and absorption and elution tests. The observations will be published in detail elsewhere.

Golgi Bodies in the Male Germ-Cells of *Vaginula maculata*

Recent works of Baker[1] and Thomas[2,3] have revived Parat's[4] vacuome theory of the Golgi apparatus in an amended form. According to them, living cells contain spheroids stainable with neutral red, each spheroid being invested with a lipoidal pellicle. Thomas[3] has claimed to show that the dictyosomes and networks, produced in nerve-cells by methods involving the use of osmium tetroxide and silver nitrate, are caused by the over-impregnation of mitochondria and spheroids and unspecific precipitation of silver and osmium. Consistently with this view Baker has proposed a new term, 'lipochondria', to replace the 'Golgi apparatus', as nothing corresponding to the network originally described by Golgi exists in the living cell. Thomas[3] has attempted a comparison of the Golgi elements of the male germ-cells of gastropod molluscs and those of nerve-cells in the light of his own view of the structure of these inclusions.

The observations made by me on the cytoplasmic organelles of the male germ-cells of the pulmonate gastropod, *Vaginula maculata*, collected at Allahabad, offer no support to the interpretations of Thomas. Each male germ-cell of *Vaginula*, spermatogonium, spermatocyte, or spermatid, contains a single Golgi body, which is easily observable by ordinary microscopy, unstained and mounted in 0·7 per cent solution of sodium chloride. No part of this structure stains with neutral red, and the entire body colours with aqueous solution of methylene blue used in a concentration of 1 : 10,000. It does not appear to contain vacuoles, stainable or non-stainable with neutral red, in its substance. Instead, it is observed to be a spherical body consisting of a denser cortex and a thinner medulla—the externum and internum. In material treated according to Ludford's modification of Mann–Kopsch (the period of post-osmication being limited to three days), the Golgi element is observed to consist of a heavily blackened thin rim and an osmiophobe interior, the latter appearing homogeneous and slightly tinged black. There is no evidence that the osmiophobe part consists of collapsed vacuoles. In cases of heavy impregnation, small spherical objects are found attached to the externum and sometimes the entire structure becomes dense black.

Although neutral red solution never stains the Golgi element, neutral red bodies do appear in the cytoplasm in the neighbourhood of the Golgi element and elsewhere. These gradually increase in size with the passage of time and do not correspond to any elements that can be made out in the unstained, living cell. Baker[5] also has recorded that the vacuoles contained in the Golgi bodies of the male germ-cells of *Helix* are not stained with neutral red, and that this dye stains vacuoles elsewhere in the cytoplasm, which are not pre-existent.

Both Thomas and Baker use the term 'lepidosome' of Parat for describing the cortical part of the Golgi body. It may be mentioned, however, that Parat[6] used 'lepidosomes', or 'lepichondriosomes', to designate the dictyosomes of male germ-cells, because he believed that these structures (the 'dictyosomes faux'), which occur around and between the neutral red vacuoles, are specially modified chondriome ('chondriome actif') especially rich in their lipoidal contents. Parat[6] wrote : "Nous avons montré que parmi les éléments imprégnables dans cette zone il fallait distinguer les éléments vacuolaires que seul Perroncito s'est montré capable de imprégner et qui sont les *vrais dictyosomes* et ces éléments mitochondriaux hypertrophiés que l'on a appelés à tort dictyosomes ; nous leur avons donné le nom de *lépichondriosomes* ou *lépidosomes*". (Italics Parat's.) Since Baker and Thomas do not hold that the lipoidal pellicle of the spheroid is of mitochondrial derivation the use of this term is scarcely justifiable.

To the Golgi body of the male germ-cells of *Vaginula* this term is inapplicable. It is true that both the Golgi body and mitochondria become equally well impregnated in Mann–Kopsch preparations and that the Golgi body is stainable with acid fuchsin and Heidenhain's hæmatoxylin after fixation in such fluids as Champy's and Flemming's without acetic acid ; nevertheless, the two inclusions differ morphologically and histochemically. The Golgi element possesses a protein substratum as is shown by the fact that it persists after treatment with a fixative like Bouin's and afterwards stains distinctly with gentian violet and such-like stains. Not a trace of mitochondria remains in such preparations. The mitochondria stain with janus green *B* and take a distinct green colour, but not the Golgi element. The Golgi element colours with methylene blue solution, which leaves the mitochondria entirely unstained. Similarly, the Golgi element stains deep blue with aqueous solution of nile blue sulphate (about 0·01 per cent) but not the mitochondria. The mitochondria occur as spherules ; no chains and filaments are observed after colouring with janus green *B*.

Palade and Claude[7,8], who believe, on the basis of their own work on the homogenates of a wide variety of vertebrate somatic tissues, that "the Golgi apparatus is a gross artefact, namely, a myelin figure, or a complex of myelin figures", dismiss the Golgi bodies of male (and also female) germ-cells as "organelles peculiar to this specialized cell-line", one of the reasons adduced for this conclusion being that they (the Golgi elements of germ-cells) can be observed in the living cell. This comes very near to Schlottke's[9] attitude that the cytoplasmic inclusions of the various kinds of cells of even the same organism are not comparable—an opinion which has very little to recommend it.

A rather remarkable feature of spermioteleosis in *Vaginula* is the fact that an acrosome does not develop in the early spermatids at all. The Golgi body, which is present in the spermatogonium and spermatocyte in the part facing the external surface of the follicle, moves in the spermatid to the part of the germ-cell facing towards the centre of the follicle.

At the same time the nucleus, which occupied a central position in the spermatogonium and early spermatocyte, moves towards the outer side. As the spermatid becomes drawn out and elongated, the Golgi element is observed to lie in the middle of its body for some time, but soon it moves away towards the tail end. In the early spermatozoon the Golgi element breaks up, its parts gradually becoming indistinguishable from mitochondria. In the elongated spermatid, in which the Golgi body has moved to the posterior end, an acrosome can be made out as a barely distinguishable structure applied to the tip of the nucleus. There is no connexion between the Golgi body and acrosome.

Gatenby[10] has described an acrosome in the spermatids of *Limnæa stagnalis*. This acrosome is, however, figured as a thin ridge on the nuclear membrane of a spermatid and appears indistinguishable from it. In this respect, conditions in the spermatids of *Vaginula* and *Limnæa* appear to be similar. It is obvious, in any case, that the secretion of the acrosome cannot be the only function of the Golgi body, since in the spermatids of *Vaginula* there is quite a large Golgi element, but it takes no part in acrosome formation.

The mitochondria remain scattered haphazard throughout the course of spermatogenesis.

A detailed account will be published elsewhere.

In Mann–Kopsch preparations, the cytoplasmic inclusion studied by Dr. Srivastava reduces osmium tetroxide and is thus blackened on the outside. Presumably it is mainly for this reason that he calls it a 'Golgi body'. Let us consider whether it is appropriate to apply the name of Golgi to a body having the characters described by Srivastava.

A wide variety of different objects in cells are sometimes blackened by the classical 'Golgi-techniques' (for example, the nuclear membrane, the cell membrane, mitochondria and granules of various kinds). It was in the nerve-cells of vertebrates that Golgi[1] described his apparatus. It is still uncertain whether there exists in the living cell a network that gives rise to the 'reticular apparatus' of classical Golgi preparations. Adamstone and Taylor[2] claim to have seen a network in the living nerve-cell of mammals by phase-contrast microscopy, though other careful workers have not succeeded in doing so. Let us assume, as a basis for discussion, that this network exists. Should we homologize Dr. Srivastava's *sphere* with this *network*? One can make the following statements about the supposed network of the nerve-cell of vertebrates with confidence:

(1) It is not easily observable by ordinary microscopy during the life of the cell.

(2) It is not stainable in life by methylene blue or nile blue.

(3) After fixation in Champy's fluid or in Flemming's fluid without acetic acid, it is not stainable by acid fuchsin nor by iron hæmatoxylin.

(4) After fixation with Bouin's fluid, it is not stainable by gentian violet.

Therefore, if the network exists, it is of an entirely different nature from the object studied by Dr Srivastava. His work thus provides support for the suggestion I made recently in these pages[3] that cytologists should discontinue the use of the expressions 'Golgi apparatus', 'Golgi body', etc. Cytoplasmic inclusions of quite different kinds are being lumped together under Golgi's name.

Gregory's "Notæ in Isaaci Newtoni Principia Philosophiæ"

DURING a recent survey of the Gregory Collection presented to the University of Aberdeen by Sir Ian Forbes-Leith, Bart., of Fyvie, I came across a bound manuscript of David Gregory's "Notæ in Isaaci Newtoni Principia Philosophiæ". A page-by-page superficial collation of this manuscript with that presented to the University of Edinburgh by J. C. Gregory, the well-known professor of the practice of medicine, led me to the conclusion that it is a somewhat later copy of the Edinburgh manuscript, the differences noted being only such as were to be expected in copying. The fact that the Aberdeen manuscript is composite as to hand, paper and binding, and the presence of a few glosses in a hand distinct from those of the text, suggest, however, that it might be worth more detailed study; particularly in view of the fact that its existence was evidently unknown to Rigaud[1] or the writer of the notice of David Gregory in the Dictionary of National Biography.

Prof. H. W. Turnbull, to whom I communicated the discovery, tells me that he was unacquainted with any manuscript except that at Edinburgh, but that he believed that the original draft was lodged with the Royal Society. Through the courtesy of Sir Harold Hartley, I have now learnt that there is a manuscript with the title "Notæ in Newtoni Principia Mathematica Philosophiæ Naturalis". I hope to examine this, since if it is indeed the original draft, it is difficult to account for the fact that it is nowhere referred to in the literature. Rigaud seems to be referring to a manuscript other than the Edinburgh, but does not state its location. In the meantime, I should be very grateful for information as to the existence of any further manuscripts of the work, or other relevant details which might help to clear the matter up. I wish to acknowledge the courteous assistance given to me by Dr. Sharp and his staff, of the Library of the University of Edinburgh.

WILLIAM P. D. WIGHTMAN

Department of History and
Philosophy of Science,
King's College,
University of Aberdeen. Aug. 10.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 12

University of London (at University College Hospital Medical School, University Street, London, W.C.1), at 5.30 p.m.—Prof. E. G. D. Murray (McGill University): "A Surmise on Some Trends in Bacteriology".*

Royal Institute of Chemistry (joint meeting with the **Fine Chemicals Group, Society of Chemical Industry**, at the Royal Institution, Albemarle Street, London, W.1), at 7 p.m.—Prof. A. Albert: "A Fresh Approach to Heterocyclic Chemistry".

Tuesday, October 13

Institute of Metal Finishing (in the Regency Room, Charing Cross Hotel, London, W.C.2), at 3 p.m.—Dr. J. W. Cuthbertson: "Education and Research in the Metal Finishing Industry" (Presidential Address).

King's College Hospital Medical School (at Denmark Hill, London, S.E.5), at 5 p.m.—Prof. E. C. Dodds, F.R.S.: "Recent Knowledge of the Endocrine Background of Malignant Disease" (Dorothy Platt Memorial Lecture).*

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Illuminating Engineering Society (at the Royal Institution, Albemarle Street, London, W.1), at 6 p.m.—Mr. W. R. Stevens: Presidential Address.

Society of Chemical Industry, Plastics and Polymer Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Discussion of Published Papers on the "Physical Chemistry of Injection Moulding".

Institution of the Rubber Industry, London Section (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. J. Dow: "The Manufacture of Adhesive Tapes".

Institute of Archæology (at the Inner Circle, Regent's Park, London, N.W.1), at 8.15 p.m.—Prof. V. G. Childe: "The Orient and Europe" ("The Panorama of Prehistory in 1953", 1).* (Further Lectures on October 20, 27 and November 3.)

Wednesday, October 14

Postgraduate Medical School of London (at Ducane Road, Shepherd's Bush, London, W.12), at 2 p.m.—Prof. A. C. Frazer: "Normal and Defective Fat Absorption".*

Institution of Electrical Engineers, Radio Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. A. Smale: Chairman's Address.

Institute of Petroleum (at 26 Portland Place, London, W.1), at 5.30 p.m.—Dr. F. P. Bowden, F.R.S.: "The Friction of Solids" (Redwood Lecture).*

The Presentation of Technical Information, Discussion Group (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Symposium on Aspects of Technical Writing (1): Prof. R. O. Kapp: "The First Draft".

Society of Chemical Industry, Food Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. R. G. Tomkins: "The Influence of Cultural Conditions on the Quality and Preservation of Fruit and Vegetables" ("Unsolved Problems in the Production of Food", 1).

Wool Education Society (at the Royal Institution, Albemarle Street, London, W.1), at 7 p.m.—Prof. J. B. Speakman: "The Preference for Wool: its Scientific Basis".

Thursday, October 15

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Discussion of Papers on "The Technique of Mine Valuation in some Special Cases" and "The Underground Water Encountered at Blyvooruitzicht Gold Mine".

Chadwick Public Lecture (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 5.30 p.m.—Mr. C. J. Regan: "Air Pollution".*

Society of Chemical Industry, Microbiology Group (at the Medical Society of London, 11 Chandos Street, Cavendish Square, London, W.1), at 6.15 p.m.—Dr. E. F. Gale: "Actions of Antibiotics in the Bacterial Cell".

Chemical Society (in the Lecture Theatre, the Royal Institution, Albemarle Street, London, W.1), at 7.30 p.m.—Dr. J. S. Anderson, F.R.S.: "The Mechanism of Reactions between Gases and Solids" (Tilden Lecture).

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. Norman White: Presidential Address.

Friday, October 16

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—General Meeting.

North East Coast Institution of Engineers and Shipbuilders (at the Literary and Philosophical Society, Newcastle upon Tyne), at 6.15 p.m.—Prof. E. V. Telfer: "Ship Model Correlation and Tank Wall Effect".

Saturday, October 17

Biochemical Society (in the Department of Chemical Pathology, Westminster Hospital Medical School, Horseferry Road, London, S.W.1), at 11 a.m.—Scientific Papers.

British Psychological Society (in the Psychology Department, University College, Gower Street, London, W.C.1), at 2.30 p.m.—Dr. David Rapaport (U.S.A.): "Theory and Investigation of Memory and Learning Reconsidered".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Head (with degree in civil engineering or A.R.I.B.A.) **of the Department of Civil Engineering and Building**—The Principal, Wigan and District Mining and Technical College, Wigan (October 15).

Lecturer (with degree or equivalent and teaching and industrial or research experience) **in Aircraft Structures**—The Principal, Royal Aircraft Establishment Technical College, Farnborough, Hants (October 16).

Lecturer (with good honours degree and postgraduate experience in physical chemistry, and suitable teaching experience) **in Physical Chemistry**, in the Department of Chemistry and Biology, Leeds College of Technology, Leeds—The Chief Education Officer, Education Offices, Leeds 1 (October 16).

I.C.I. Research Fellowships in Industrial Relations—The Secretary of the University Court, The University, Glasgow, W.2 (October 17).

Senior Lecturer (with high academic and research qualifications) **in Organic Chemistry**—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (October 21).

Lecturer (woman) **in the Department of Education**—The Registrar, University College of Wales, Aberystwyth (October 24).

Assistant Engineer (A.M.I.C.E., and preferably with a degree in engineering) **in the Native Engineering Department**, Southern Rhodesia Government—The Secretary, Rhodesia House, 429 Strand, London, W.C.2 (October 30).

Chair of Physical Chemistry—The Registrar, The University, Nottingham (October 31).

Lecturer (well qualified in pure or applied science, and experience in the gas or other branches of the fuel industries, and preferably with a knowledge of oil technology) and an **Assistant Lecturer** (well qualified in pure or applied science, and preferably with industrial experience) **in Gas Engineering and Fuel Technology**—The Registrar, The University, Leeds 2 (November 2).

Senior Lecturer in Physical Metallurgy at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 6).

Senior Lecturer in Physical Metallurgy at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 6).

Nuffield Research Fellow in Oral Biology—The Registrar, The University, Leeds 2 (November 9).

Chair of Logic and Metaphysics, Chair of Botany and **Chair of Geology**—The Secretary, Queen's University, Belfast (November 20).

Scientific Officer (Biochemistry) for research in problems in children—The Secretary, Queen's University, Belfast (November 30).

Lecturer in Biology and a **Demonstrator in Biology** (with honours degree, with zoology as the principal subject) in the Department of Zoology and Comparative Anatomy—The Dean of the Medical College, St. Bartholomew's Hospital, London, E.C.1 (December 1).

Assistant Meteorologist (with H.S.C. or equivalent in mathematics or physics, and preferably with forecasting experience) with the Mauritius Government—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M3B/32530/TA.

Engineer (preferably with honours degree in engineering or physics) **in the Television Section** of the Designs Department, to take charge of design of major items of equipment used in television studios and control rooms; and able to produce original work—E.E.O., B.B.C., London, W.1, quoting E.782.

Entomologist (with sound knowledge of methods of biological assessment and capable of undertaking specialized research) with the Pyrethrum Board of Kenya, to take charge of Biological Laboratories in Nakuru, and lead an entomological team working in conjunction with chemists on problems connected with the pyrethrum industry—Box "SK/82", c/o 95 Bishopsgate, London, E.C.2.

Experimental Officers and **Assistant Experimental Officers** (with at least H.S.C. (science) or equivalent, and further qualifications in mechanical, electrical or electronic engineering, physics or mathematics may be an advantage) at the Royal Aircraft Establishment, Guided Weapons Department, Farnborough, for work on design, development and performance on new weapons and associated guidance and control systems; instrumentation of flight trials and investigation of trial results—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.237/53A.

Fisheries Officers (preferably with honours degree in natural science with emphasis on biology) in Nigeria, to demonstrate and develop simple fish farming in collaboration with a Fish Farmer and to investigate the relative suitabilities of different techniques—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.149/14/02.

Mechanical Engineers (with good general engineering design experience, preferably in chemical plant or power plant); **Electrical Engineers** (with wide experience in preparing specifications for the installation of electrical services, and preferably in the supervision of installation work); **Instrumentation and Control Engineers** (with wide experience in the design and installation of control and recording circuits and servo-mechanisms), to assist in the design, construction and development of nuclear reactors—The Establishment Officer, Atomic Energy Research Establishment, Harwell, Berks, quoting "Eng. 93/53".

METEOROLOGIST (with university degree in mathematics or physics, or equivalent qualifications, and extensive forecasting experience, preferably tropical, for aviation and agricultural purposes, and sound knowledge of all duties in a territorial meteorological service) in Nyasaland, for organization and administration of aviation, weather and public forecasting service at Blantyre airport, and research into problems arising from the development of the meteorological service—The Director of Recruitment (Colonial Office), Sanctuary Buildings, Great Smith Street, London, S.W.1.

METEOROLOGIST (with first- or second-class honours degree in physics or mathematics, and two years experience in aviation forecasting) in Northern Rhodesia—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.57/3/01.

PHYSICISTS and ENGINEERS, (*a*) SCIENTIFIC OFFICER grade (with first- or second-class honours degree or equivalent in physics or engineering) for research and development in connexion with gyroscopic and allied instruments, Ref. A.247/53A; (*b*) and (*c*) EXPERIMENTAL OFFICER or ASSISTANT EXPERIMENTAL OFFICER grades (preferably with practical experience of development in light mechanical or electro-mechanical field) to assist in above duties, Ref. A.248/53A; (*d*) EXPERIMENTAL OFFICER grade (with H.S.C. (science) or equivalent, but H.N.C. or degree in physics may be an advantage) for research and development, mainly in photographic optics, Ref. A.249/53A, in the Instrument and Photographic Department, Royal Aircraft Establishment, Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

PRINCIPAL and SENIOR SCIENTIFIC OFFICERS (with first- or second-class honours degree in mechanical engineering with metallurgical experience, or first- or second-class honours degree in metallurgy with engineering experience), at the Atomic Energy Research Establishment, Harwell, for fundamental studies of nuclear reactor design, involving assessment of metallurgical and materials problems relative to engineering design requirements—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting C.529/53A.

RESEARCH ASSISTANT and a RESEARCH STUDENT (honours graduates in science and engineering) to work on physical problems connected with the combustion of droplets—The Registrar, Imperial College, London, S.W.7.

RESEARCH FELLOW IN SUGAR CHEMISTRY in the Department of Sugar Chemistry and Technology, Imperial College of Tropical Agriculture, Trinidad—The Secretary, The Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2.

SCIENTIFIC OFFICER (with honours degree in biochemistry or physiology, and preferably with previous experience in biological research) IN THE NUTRITION DEPARTMENT of the National Institute for Research in Dairying, to take part in work that will include the determination of the biological value of proteins, the study of calcium and phosphorus metabolism using radioactive tracers, vitamin D assays and general nutritional experiments with rats—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting 53/16.

SCIENTIFIC OFFICERS and SENIOR SCIENTIFIC OFFICERS (with first- or second-class honours degree or equivalent, in physics, mathematics or engineering, and for the senior grade, at least three years post-graduate research experience) for project assessment groups at the Royal Aircraft Establishment, Farnborough, and at London Headquarters—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.161/53A.

SENIOR SCIENTIFIC OFFICER or SCIENTIFIC OFFICER (with first- or second-class honours degree in mathematics or astronomy, and an interest in celestial mechanics, spherical astronomy or numerical computation, and preferably with research experience in at least one of these subjects) IN H.M. NAUTICAL ALMANAC OFFICE, Royal Greenwich Observatory, Herstmonceux, Sussex, for work in the fields of celestial mechanics and positional astronomy—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.252/53A.

TRAINING FOR MANAGEMENT

THE discussion on training for management, arranged jointly by Sections F (Economics) and L (Education) of the British Association during the recent meeting in Liverpool, which was opened by Sir Charles Renold and Prof. R. S. Edwards, like other recent discussions, notably at conferences arranged by the Federation of British Industries, emphasized the importance of co-operation between industry and the universities in such training in order that the standard of management in industry may be raised. While industry should pay more attention to systematic training of its recruits, Sir Charles Renold urged that the most effective results would be obtained by co-operation between industrial companies and a university in running joint training schemes. The objects of such a training scheme for graduates entering industry, in his view, were to give the graduate the feel of industrial life and to help him to find his feet, and also to give him a general understanding of the basic features of the company's business, as well as the opportunity of developing so that his particular bent was revealed and the foundations were laid for specialized knowledge and experience.

Sir Charles thought it was important that as much as possible of the university man's training should consist of the execution of specific jobs for which he would be definitely responsible, and the scheme he suggested was one extending over three years, partly with an industrial firm and partly at a university. The trainees would be engaged by the company and would attend a university as sponsored students, where their training would aim at providing a background understanding of industry which would give point to the practical work, and also supply more specialized knowledge in fields where the chosen career made it desirable. Such a course would, he thought, enable the recruit to climb the ladder faster as well as improve the calibre of management, though it would only lay the foundations for general management, the capacity for which would come to light in later years.

Commenting on this scheme, Prof. Edwards said that, while there was room for major experiment, we have not yet reached the stage when the number of applicants of good quality exhausts the training facilities available. He believed that the universities could match any probable level of demand for postgraduate training in business administration ; and if the demand for places increased rapidly, he thought it would be wiser to dilute temporarily the discussion method of teaching with more lecturing, rather than to establish new departments and additional posts and staff them at a level below what is in Great Britain regarded as appropriate to university work. If thirty or forty leading businesses each seconded one trainee to a university postgraduate course in administration in each of the next three academic years, industry could then judge for itself whether or not an academic year during business training was worth while. Prof. Edwards suggested that this was a scheme for which

Counterpart Funds provided by the United States under the Benton–Moody Amendments might very appropriately be used to the extent of contributing to firms seconding men for such postgraduate training in European universities a grant equal to half the salary of each man accepted for a course.

The contribution which training schemes of this type could make towards raising the calibre of management, avoiding frustration on the part of the recruits and in assisting industry to attract and keep men of the calibre it desires was generally recognized; but the difficulties that may arise in these proposals were not really explored. Both Sir Charles Renold and Prof. R. S. Edwards were emphatic that university graduates are not the only source of potential general managers, and Sir Charles said specifically that it would be fatal to the morale of an organization if it were believed that there was no chance of promotion from the 'shop-floor'. Prof. Edwards proposed that the scheme of seconding men to a university postgraduate course should not be limited to graduates. Nevertheless, in view of the increasing extent to which the abler pupils leaving school now enter the university, as one speaker reminded the meeting, it may well become in practice increasingly difficult for industry to promote its managers from the shop-floor, however wide open the door may remain at least in theory.

What this amounts to in practice is that selection is liable in future to take place to an overwhelming extent on leaving school: the managers in industry will develop in general among the group that enters the university. The significance of this factor seemed to be missed in the discussion, or the really startling indictment of the university graduate which Prof. F. W. Paish slipped out in opening the discussion would scarcely have escaped comment. In a reference to the qualities of the university graduate, Prof. Paish remarked that he is sometimes less teachable and less easy to discipline than those who have entered industry direct from school. Unless, however, the graduate carries with him from the university the inquiring mind, the very purpose of a university education has failed; what, above all, is expected of the graduate is not a mind full of facts but an open mind that has learned to handle facts and where to seek them. If the universities are not providing industry with men who have been trained to think, to be critical and to exercise initiative, but are supplying appreciable numbers of graduates with the closed mind of which Prof. Paish spoke, the discussion of training for management should start by inquiring very closely into the form of undergraduate training.

Postgraduate training will do little if the university has really failed to promote the imaginative consideration of the general principles underlying an intellectual career which A. N. Whitehead insisted is the chief function of a university in the preparation for such a career. It may well be, however, that training for management needs to be considered rather more closely in relation to undergraduate training generally, in view of the probability that industry will in future have to recruit its managers in the main from the university rather than the shop-floor. If confidence is to be maintained that a managerial career is open to all who can show that they possess the requisite capacity, it is in the university that there must be wide opportunities of acquiring the particular auxiliary techniques and the wide general knowledge that a manager may be called upon to exercise. This much is clearly recognized in the provision at the Imperial College of Science and Technology in London of general lectures on ends and means in science and on legal and economic subjects for postgraduate students of science and technology, and also in the curriculum of the new University College of North Staffordshire.

It should also be noted that at the Federation of British Industries Conference, at which he raised the question of the increasing dependence of industry on the universities for its managers, Dr. Eric Ashby also voiced the misgivings of many of his academic colleagues as to the extent to which management could be taught. There are techniques which a manager must use, and there is much technical knowledge which he requires in evaluating particular situations and making his decisions; but ultimately management is an art to be learnt by apprenticeship, by working and studying under competent practitioners of the art.

This aspect scarcely received sufficient attention in the discussion at Liverpool, and it is frequently ignored. Its importance, however, has been emphasized recently in several ways. It was apparent from the evidence submitted to the Select Committee on the Nationalised Industries that the misgivings with which some of the witnesses regarded the proposal to set up a Standing Committee for the Nationalized Industries to inform Parliament more fully about the industries, though not to control them, was due largely to fears that the quality of management in those industries would be adversely affected. Fuller public accountability would thus only be secured at the expense of managerial efficiency.

There is much to support this view in the latest report on the nationalized industries of Great Britain which has come from the Acton Society Trust*. Undertaken as a further study in decentralization, in extension of those already made by the Trust, the report is concerned especially with the changed functions and status of what are described as the operational managers, and above all, whether they are given sufficient freedom of decision to carry out their job satisfactorily. Inevitably, a measure of central planning, co-ordination and specialization involves some restriction of the operational manager's powers. The Acton Society Trust examines the crucial questions whether the actual restrictions are more than are necessary to achieve the desired co-operation, and whether the degree of restriction is such that the operational manager feels frustrated.

This examination of the practical possibility of reconciling the needs of central control and of local autonomy, with its frank facing of the question whether achievement of one means the sacrifice of the other, makes the report an admirable complement to that of the Select Committee. It should be said at once that this study of the position of an area general manager in the coal industry, of a power-station superintendent, and of district managers in the Road Haulage Executive and the Welsh Gas Board respectively is not a little disturbing. It indicates, indeed, some of the factors of which account should be taken before a sound judgment can be reached as to whether the need for greater public accountability is only a passing phase which the nationalized industries themselves will rectify as they become established and less disturbed by political debate. But it emphasizes also the extent to which critical and constructive thinking about the whole function and conception of management in industry is required if we are to achieve the degree of widespread co-operation and mutual understanding, particularly between the specialized types of manager now in existence, upon which effective modern management depends.

---

* Management under Nationalisation: Studies in Decentralisation. Pp. 79. (London: Acton Society Trust, 1953.) 7s. 6d.

In these studies by the Acton Society Trust, the term 'decentralization' is used to refer only to the devolution of authority from the centre of the organization to the periphery. Their primary objective is to convey in concrete terms the actual impact of nationalization on the operational manager responsible for the day-to-day operation of a producing or service unit or units. The Trust believes that the views of the operational manager, which will not necessarily be shared at other levels of management, are facts which should be taken into account in planning or assessing any reorganization, for the problems of the operational manager are a vital factor in the future development of the industries.

Although the report attempts no more than sketches of the point of view of the four representative managers already indicated, the portrayal is done skilfully and with imagination; it should stimulate fresh thinking and provoke new ideas as to the dangers to be avoided and the objectives to be sought.

The major failure of the nationalized industries of Great Britain in regard to their operational management, in the view of the Acton Society Trust, is the failure of the boards to make it clear to the manager that appropriate action by the higher management will follow the operating results of his unit. As the report properly observes, judgment by results and the appropriate response to failure or success by the higher management may well be the best guarantees of efficiency and enterprise. "If the Boards fail to dispel the belief that no man will be removed no matter how inefficient, the present expectations of the public industries may never be realised."

That, of course, cuts right down to all levels and encounters a great difficulty in the fact that the boards are, almost without exception, the sole employers in a particular industry. Even without the difficulty of proving inefficiency before a formal committee, which the establishment of protective disciplinary codes usually means, finding a balance between reasonable security and adequate incentives is a formidable problem. The centralizing tendencies are carried further by the influence of Parliamentary accountability and the representation of consumers. The demands of a nationalized industry may, in fact, involve restrictions on management which are unique and which no board can easily relax without prejudicing the purposes for which public ownership was introduced.

Here lies the greatest need for fresh and constructive support, and it is interesting to note that very similar conclusions have been reached by other disinterested and detached observers. Sir Douglas Copland, in his presidential address to the Australian and New Zealand Association for the Advancement of Science at Sydney in August 1952, dealt with the broad question of authority and control in a free society; he commented on these same difficulties and suggested that the social scientist has a heavy responsibility for devising means of promoting initiative and of fostering the enterprising spirit in all fields of public administration. Extensions of authority and control require a solution of this basic problem if society is to remain free and enjoy the forms of collective enterprise required for economic progress and social welfare.

There is thus little in this report to justify the view that the problems of the operational manager can be dismissed as essentially 'teething troubles', and here the Acton Society Trust reminds us that the discussion is also concerned with the vital question—How are the managers of the future to be attracted and trained? There is already evidence that, in the nationalized industries and elsewhere, centralized organization fails to attract the able man, partly because it affords few opportunities for exercising initiative and responsibility. Unless managers are allowed to manage, it is vain to argue that until the able man turns up decentralization is impossible.

To recognize these conflicts is the first step towards an attempt to resolve or reconcile them. Any policy of decentralization for the nationalized industries must first attempt to understand and to reconcile the genuine conflict between the demands of Parliamentary accountability and public control on one hand, and the traditional conception of managerial initiative on the other. No concrete proposals are made in this report; but four lines of advance are indicated which, while primarily intended to stimulate thought about the nationalized industries, have their bearing on industrial management generally and on an aspect of training for management which was overlooked in the British Association discussion at Liverpool. First, it is suggested, a better balance should be sought between public accountability and financial responsibility on one hand and managerial flexibility on the other. Next, new methods are required of selection and training for management adapted to the needs of a large-scale organization. Third, and probably, in nationalized industry, most important, confidence must be strengthened between managers at all levels through regular contact. Lastly, attempts should be made to improve measuring techniques, by, for example, the development of new objective criteria enabling the superiors not only to judge their subordinates but also the subordinate managers to judge themselves.

Obviously training for management must take account of all these lines of thought, and above all of those new implications, largely unexplored as yet, of the conception of responsibility in industry. No scheme of co-operation between industry and the universities can of itself contribute much towards the establishment of that confidence throughout industry on which effective management largely depends, nor will it avoid frustration if from any cause those trained are not allowed to manage. Such schemes can, however, do much to provide industry with men who are competent to use their opportunities of establishing confidence and of working harmoniously and effectively with others, whether specialists or not, and who may be expected to contribute something to the constructive thinking about problems of decentralization and of the reconciliation of control and initiative upon which the Acton Society Trust and Sir Douglas Copland alike insist.

What is important, therefore, is that the limits of training for management should be clearly recognized, as well as its possibilities. There are techniques that can be acquired so that the trainee is better equipped to deal with the problems which he will encounter when he comes to exercise managerial responsibilities; but apart from this it could well be argued that every industrial recruit, at least of the status of graduate, should be given something of the training that Sir Charles Renold suggests. To give it solely to those intended for managerial posts may well have the very effect on morale, under present conditions, that Sir Charles wished to avoid.

For that reason it is possible that the most essential preparation for management is that which should be acquired in the normal course of a university education. Not a few of the most serious mistakes in organization and administration in Great Britain in recent years, whether in government or in industry, have been made through lack of the philosopher's habits of thought and his ability to view a situation as a whole and the changing effects on it of each individual action. Too often there have been neglected the simple principles of governing men which have been displayed so clearly by Sir Ernest Barker, for example, or illustrated by Commander A. H. Leighton in his book "The Governing of Men". That book, it may be noted, came from a university press, and if the universities have adequately discharged their fundamental task and supplied industry and government with men imaginatively alive to the human issues underlying the decisions they are called upon to make, who have been stimulated and trained to think strenuously about the great issues of right and wrong, of liberty and government, and who are capable of making balanced judgments, industry is unlikely to find it a heavy task, either alone or in postgraduate courses in collaboration with the universities, to supply whatever further training is required to enable its recruits to perform skilfully and magnanimously the varied technical or managerial tasks that may be set them. Alert, receptive and sensitive minds are the right basis for training in management, and when this is ensured there should be the less danger, either in industry or in government, of neglect of understanding, or failure to dig deep the channels of assent. There should then, too, be little danger of excessive preoccupation with either the selection or the training of managers and administrators deflecting the attention of industry or of government from the graver and more urgent problem to-day of securing the conditions in which effective management and administration are possible.

LEEUWENHOEK'S LETTERS

The Collected Letters of Antoni van Leeuwenhoek

Edited, illustrated and annotated by a Committee of Dutch Scientists. Vol. 4. Pp. ix + 384 + 28 plates. (Amsterdam: Swets and Zeitlinger, Ltd., 1952.)

THE stately progress of this opulent edition is severely deliberate; but happily no diminution of its initial vigour and purpose can be detected. Four out of the projected twenty volumes have now been printed, the first three appearing in 1939, 1941 and 1948. The preparation and publication of these four volumes, therefore, having extended over some sixteen years, the completion of so difficult and expensive an enterprise, if pursued at the same leisurely momentum, will not benefit many of us now living. The present Vol. 4 includes letters 70–81 inclusive (old numbers 37–42); but six of these are very brief communications of no scientific interest, though they are properly retained for the sake of completeness. The most important of the great variety of topics dealt with, arranged in chronological order from January 1683 to July 1684, explore problems of generation, the anatomy of the flea, spermatozoa as the source of the fœtus, histology of the blood, the flora of the saliva, histology of the epidermis, blood capillaries and lymph vessels, comparative histology of the lens of the eye in various vertebrates, red blood corpuscles of birds and amphibia, structure of negroid skin, structure of the brain in birds and mammals, and the scales of fishes such as the eel, and age determination thereby.

The letters are followed by an essay on Leeuwenhoek's ophthalmology written by Prof. W. P. C. Zeeman, in which the author claims that modern methods of investigation have "not been able to add much of essential importance" to Leeuwenhoek's researches on the lens capsule and lens of the vertebrate eye. Finally, there is Miss J. I. H. Mendels's very interesting discourse on Leeuwenhoek's command of his own language; but only those parts of this enlightening analysis which would be useful to the foreign reader have been translated into English. She rightly claims that Leeuwenhoek's Delft dialect is a valuable source of the spoken Dutch language of the seventeenth century, and is therefore of importance to the student of that dialect.

The volume is completed by useful bibliographies and brief lives of authorities quoted, and all the surviving original illustrations are reproduced together with relevant modern figures for purposes of comparison. There is a good index. Dr. A. Schierbeek of The Hague, whose energy and enthusiasm are inexhaustible, is the learned editor.

The complete and adequate English translation of all the letters will be gratefully welcomed by those unfamiliar with the Dutch tongue. Such textual annotations as are necessary for the clarification of Leeuwenhoek's numerous difficult passages, and without which the translation would lose much of its value, are provided by some nineteen eminent authorities. Printer's errors occur, it is true; but when the sense is not compromised they may be left to the corrective pencil of the reader. On the other hand, the following mistranslations and errata have been noted: p. 5, par. 2, for 'edited' read 'published'; p. 11, Juny is Leeuwenhoek's Dutch and not English; p. 23, par. 2, insert 'which was the' before 'reason'; footnote 39, for 'two germinate' read 'paired'; footnote 41, for 'entwine' read 'radiate over'; p. 37, footnote 67, 'indissoluble' is obsolete in English in the sense of this paragraph; p. 49, line 2, for 'cause' read 'case'; p. 69, footnote 27, for 'who did not yet dispose of a staining-method' read 'without the assistance of staining methods'; p. 71, footnote 30, for 'the rule of dominants' read 'dominance'; p. 73, footnote 32, the nematode Leeuwenhoek saw in the frog was probably *Oxysomatium longespiculum* not *Oxyurus* (*sic*); p. 121, this letter is correctly dated in the reviewer's copy of the *Phil. Trans.*; p. 145, last line read 'dermis'; p. 175, line 11, read 'purgative'; p. 189, footnote 35, 'with' is redundant; p. 211, last line, for 'observing it in parcels' read 'observed its parts'; p. 213, footnote 7, this quotation is not literal but modified; p. 217, footnote 15, for 'laying' read 'lying'; pp. 241 and 311, why adopt the French 'mouches volantes' in an English translation instead of the Latin 'muscœ volitantes', which is the earlier equivalent in English scientific texts; p. 245, the 'black Moorish girl' was doubtless a negress—an assumption supported in the 1708 edition of Sewel and by the context; p. 259, the 'nerve-fibres containing marrow' are in English 'medullated nerve fibres'—*merghoudende* in Dutch and *markhaltig* in German; p. 265, line 2 from bottom, for 'flown' read 'flowed'; p. 337, Blasius's dates are *c.* 1625–92.

We heartily congratulate the Leeuwenhoek Commission on its courageous decision to continue its task at the same high level of production without flinching from the far greater difficulties which now confront them.

F. J. Cole

NUCLEAR STABILITY

Nuclear Stability Rules

By Prof. N. Feather. (Cambridge Monographs on Physics.) Pp. ix+162. (Cambridge: At the University Press, 1952.) 20*s.* net.

THE study of nuclear structure continues to attract the attention of a large and growing body of physicists; between one and two hundred papers are published monthly, each containing new information about particular nuclei. With such a mass of information produced at such a prodigious pace, the process of collecting, sifting, analysing and presenting the material in a manner which makes the details readily accessible and the general trends clearly discernible becomes a task of vital importance. Mere accumulation of data, however thorough and well-ordered, is not sufficient; nor is the occasional review which may present some aspect of the new information in relation to a particular theoretical background; and in both of these respects the needs of nuclear physicists have been well met in recent years. What is often wanted is a compact and comprehensive survey of a wide range of experimental material, and it is to the worthy task of providing such a survey that Prof. Feather addresses himself. Within the scope of a Cambridge monograph he presents a coherent, readable, up-to-date account around the theme of nuclear stability.

There are two distinct aspects of nuclear stability to be considered: first, the energetics—what modes of spontaneous disintegration are possible for a particular nucleus. Secondly, knowing a particular mode of disintegration to occur, and the energy change associated with it, the significant property of the process is the characteristic probability or rate. The major part of the book under review is concerned with establishing and examining regularities in the above two respects for the two commonest types of nuclear instability, α- and β-decay. In addition, the book opens with a short discussion of the practical limitations to the observation of instability, and an account of the range of charge and mass numbers for which stable nuclei occur. It concludes with a brief note about the instability of heavy nuclei as regards 'fission'.

Throughout, the author avoids sophisticated theorizing on the facts, adhering to his declared aim only "so to marshal the facts that the theorist is most likely to be inspired by valid—even 'correct'—ideas on contemplating them". Nevertheless, some theory does make an appearance; and if such a book is to appeal to readers other than specialists in this particular field, then the function of the theory both in the process of marshalling the facts and interpreting them must be clearly brought out, and it is questionable whether the author's choice and arrangement of material always serves this purpose well. For example, the regularities in α- and β-decay energies are particular manifestations of some features of the nuclear mass 'surface' (mass regarded as a function of the two variables A, Z), and can be more readily appreciated if some picture of this surface as a whole is presented, which would involve a discussion of data other than of the α- and β-decay processes themselves. In another respect, the presentation of detailed algebraical manipulations (particularly in Chapter 3), the interesting features would stand out more clearly if the details were omitted. In the treatment of regularities of life-times of α- and β-decay processes, the general theoretical interpretation of the dependence of decay probabilities on energy is, in both cases, assumed, and the information should therefore be presented in such a manner as to expose the regularities which are of interest because they are *not* accounted for by the straightforward part of the theory. In particular, the many diagrams showing the relationship between β-decay constant and energy could be condensed to a more compact presentation of the 'reduced' decay constants ('ft' values) for different β-emitters, in which the irrelevant energy-dependence has been removed.

A controversial issue inevitably raised by such a book is that of notation. Here one can commend the general restraint shown in introducing new terminology, and at the same time indicate where more drastic action would have been welcome. The specification of nuclei sometimes by the numbers A, Z and at other times by N (neutron number) and Z, and the corresponding duplication in the description of the 'even–odd' characteristics, are surely not both necessary; and the unconventional use of the word 'parity' in this connexion is sometimes undesirable. The phrase 'nuclear species' is scarcely an improvement on the now common 'nuclide'.

Many readers of this book may wish that the author had adopted a rather broader treatment, by incorporating a wider range of relevant experimental material (for example, the systematics of the masses of stable nuclei and their actual observed abundances are relevant topics); and also giving more indication of how the facts elicited are related to current theories of nuclear structure. However, this would probably have resulted in a much larger work, and Prof. Feather hints at the restraint he has had to exercise in order to keep within the limits he has set himself. In dealing with the "magic numbers", he remarks (p. 26), "the temptation is great to embark at once on an ambitious attempt to find their interpretation in a 'shell model' . . . that temptation we shall for the present resist". But by the time all the experimental material is presented, there seems to be no space in this book for this fuller interpretation, and the reader must content himself with the valuable presentation of the material itself. S. DEVONS

LOCOMOTION OF ANIMALS

How Animals Move

By Prof. James Gray. (The Royal Institution Christmas Lectures, 1951.) Pp. xii+114+15 plates. (Cambridge: At the University Press, 1953.) 16s. net.

ABOUT twenty-five years ago Prof. James Gray turned from his classic researches on cytology to start his investigations on a very different subject, the mechanics and physiology of the locomotion of animals. Since then the vigorous Cambridge school of research into this aspect of zoology has grown up around his pioneer work, and a large volume of literature records the results of its experiments and observations on all groups of the animal kingdom from Protozoa to Mammalia. Prof. Gray has not yet given the scientific world a book digesting and integrating the great mass of new knowledge that he and his colleagues have discovered; but in the meantime he has done something even more difficult—he has written a book for children that sets forth the basic principles of the subject clearly and simply to make a most fascinating story.

The book introduces animal locomotion with a consideration of certain simple laws of mechanics and, using the motor-car and the lever as familiar examples to lead up to the more complicated mechanisms of animals, shows that all locomotion is governed by the same mechanical principles. Muscular contraction is described; and the action of the motor and sensory nerves, and the proprioceptor sense organs, including the semi-circular canals, is demonstrated by analogy with the controls and dashboard instruments of a machine. After these foundations are laid, the remaining five chapters discuss animals themselves and develop the story of locomotion from swimming, through walking and running, jumping and creeping, to gliding and flapping flight.

Prof. Gray avoids writing-down, and by the aid of clear diagrams and interesting examples he makes his technical details easily understood and shows how the structure of an animal is correlated with its way of life, though he does not, of course, venture to speculate whether structure determines function or vice versa. His well-chosen illustrations of the various points that he makes hold the attention and are full of surprises for the newcomer to the subject. The chapter on swimming demonstrates how unreliable the eye is when observing movement, and shows the necessity for using recording instruments when accurate analysis of phenomena is desired. The speed of a fish darting through the water is much less than it appears to be; a trout dashing away with the fly and making the reel scream round is taking the line out at only 3 m.p.h., and a heavy salmon putting a pull of 1 lb. on the line necessitates a force of 12-13 lb. on the hands at the butt to hold the rod stationary. But the acceleration of a fish is great: starting from rest the maximum speed is attained in 1/20 sec., an acceleration of 140 ft. per sec. per sec. A 600-lb. sword-fish travelling at 10 m.p.h. and colliding head-on with a wooden ship moving at the same speed strikes it with a force at the tip of the sword of more than 4½ tons—the surprising thing is not that the sword penetrates the wood, but that it does so without itself being smashed in the process.

Thus the theme is continued: the electrical field surrounding *Gymnarchus* that allows it to find its way through muddy water; the evolution of legs from fins; the paces of terrestrial animals; how a kangaroo could jump over St. Paul's Cathedral if its leap were proportional to that of a flea, and why it cannot; the mechanics of the snake's movements; the flight of pigeons, albatrosses and bats; ultrasonic echo-location; and the function of halteres.

The author says in concluding his book: "The more we learn about living animals, the more beautiful their activities appear; and in a human world so much concerned with ugly engines of destruction, the concept of natural beauty provides welcome relief". Here speaks the true naturalist in the best sense, and he has been so successful in expounding his subject that few who take up his book will be able to put it down until they have devoured it all. This is popular science as it should be, and one hopes that Prof. Gray's little masterpiece will have the wide success that it deserves.

L. HARRISON MATTHEWS

PSYCHOLOGY OF PERSONALITY

The Logic of Personality

By Bernard Mayo. Pp. 188. (London: Jonathan Cape, Ltd., 1952.) 10s. 6d. net.

THE main virtue of Mr. Mayo's book lies in its trenchant logical analysis of the question: What is personality? He shows that certain meaningless questions about personality can be replaced by meaningful ones. At first sight this may not seem a very impressive contribution. We begin to see its importance, however, when we follow the author in tracing the consequences of his views for discussions of personality in relation to art, ethics, and certain linguistic usages, and to the cognitive bias in philosophical theories of perception. The book could be studied with profit by personality testers, factor analysts, thematic apperceptionists, and students of *Rorschachiana* and the new journal *Szondiana*.

Mr. Mayo's discussion is marred on occasion by curious ideas about the psychology of personality. He supposes that the psychologist is only concerned with indirect knowledge, for example, such as may be embodied in or derived from testimonials, not with direct interpersonal knowledge. He thus appears to be confusing metaphysical with empirical analysis, an error he could have avoided by becoming familiar with modern interpersonal theory. Much blood has been shed over the hyphen in the word 'inter-personal'. The battle between hyphenated and hyphenless interpersonalists is an attempt to decide the question whether the basic datum is a more-or-less self-contained individual entity, on one hand, or *relationships* between persons on the other. If the basic datum for empirical study is a set of relationships with other people, as the hyphenless school of thought contends, then the searching for individual entities can be left to the metaphysician.

Mr. Mayo's ideas on the measurement of personality are limited to the notion of scales for rating opposite traits and do not therefore need to be taken very seriously. His views on the 'self' will provoke more criticism. He argues that an entity called 'the self' is based on bad grammar, because there is no precedent for the use of the word 'self' as an independent noun capable of being the subject of a verb. He asserts furthermore that the problem of the self, even if it were genuine, would be irrelevant to the question of personality. This dismissal of an empirical problem as a verbal error is too facile a solution. One may add that in view of the uniqueness of the notion of self an argument based on lack of precedent scarcely carries conviction.

It is a pity Mr. Mayo has not confined himself to purely logical or philosophical questions. His failure to prevent the intrusion of empirical problems into a formal discussion spoils an otherwise valuable essay.

JOHN COHEN

HYDRODYNAMICAL THEORY OF DETONATION AND SHOCK WAVES

Detonation in Condensed Explosives

By J. Taylor. (Monographs on the Physics and Chemistry of Materials.) Pp. xi+196+10 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 25*s*. net.

État actuel et valeur de la théorie hydrothermodynamique des explosions et des chocs

Par Dr. S. Travers. Première partie: Les ondes de choc pur et la compressibilité par choc sans combustion. Pp. v+116. 900 francs. Deuxième partie: L'Épaisseur des ondes de choc et le mécanisme de l'inflammation dans les ondes de combustion. Pp. ix+294. 1900 francs. (Paris: Éditions Eyrolles, n.d.)

THE theoretical and experimental studies of explosion and detonation carried out during the War and afterwards have served to focus attention on the physico-chemical changes occurring in the reaction zone of an explosive, and have led to a more precise formulation and extension of the classical hydrodynamical theory of detonation. It will be recalled that the simple form of the theory assumes the whole chemical reaction providing the energy necessary for the detonative process to occur within a narrow zone, the detonation front, moving with uniform velocity into the stationary explosive. Chapman and Jouguet further assumed that disturbances in the gas immediately behind the front travel at the same speed as the front, giving rise to a progressive wave of finite amplitude. It is clear, however, that the velocity of detonation must be influenced by the mechanical reaction of the gases streaming away from the front on the gas immediately behind it, and Taylor has formulated and solved the hydrodynamical equation for special cases where the flow field has symmetry.

Another important development relates to the behaviour of shock waves, produced with and without combustion, in solids, liquids and gases. The work of Hugoniot on shock waves in air has been extended by Becker to liquids and by Travers to solids, while Taylor has dealt with the case of blast waves produced by the release of a very large amount of energy unaccompanied by the generation of gas.

These theoretical advances have been accompanied by improvements in the experimental methods for measuring explosion and detonation velocities, and for observing the sequence of events both before and after the passage of explosion waves. As a result, we now have a much better understanding of the physical and chemical changes associated with explosion and detonation phenomena, and it is possible, with some confidence, to design and develop new explosives to meet the more exacting specifications demanded to-day by industry and the Services.

The two books here reviewed deal with somewhat different aspects of the subject. In "Detonation in Condensed Explosives", Mr. Taylor gives, within the compass of some two hundred pages, a brief description of the propagation of detonation in condensed explosives and an outline of the methods for calculating the numerical values of the detonation parameters. The examples quoted are chosen from commercial blasting explosives and much of the data has been obtained in the research laboratories of the Nobel Division of Imperial Chemical Industries, Ltd.

The ground covered in the monograph is extensive, and the theoretical treatment is in consequence somewhat superficial. The chapters on the hydrodynamical theory of detonation and on detonation in explosives where products may consist of gases only or may include a condensed phase are, however, clearly and concisely written and the methods of calculation are carefully explained. The text is well illustrated and a short bibliography is provided.

The two volumes by Dr. S. Travers are compiled from papers in the "Mémorial de l'Artillerie française", and are devoted to a detailed examination of the hydrodynamical theory of explosion and shock waves. The first volume deals with pure plain shock waves produced by mechanical compression without combustion, the basis of the treatment being the work of Hugoniot on waves in air and of Becker on waves in liquids.

The second volume deals with the dimensions of shock waves and the mechanism of inflammation in combustion waves, and contains an excellent historical review of the early work of Rankine, Riemann, Rayleigh, Chapman and Hugoniot.

Dr. Travers has generalized Becker's treatment to include the case of shock waves in solids and gives a method of graphical representation which provides an admirable picture of the physical changes occurring in the case of waves produced with and without chemical reaction.

The mathematical treatment of the complex phenomena associated with detonation is clearly and concisely presented, and references to the literature are complete up to 1953.

D. M. NEWITT

THE PLATINUM METALS

By A. R. POWELL, F.R.S.

IN April 1803 there appeared in the window of a mineralogist's shop in Soho an anonymous leaflet offering for sale a new metal called palladium. In the following year William Hyde Wollaston announced his discovery of another new metal which he called rhodium, and he afterwards admitted in a letter to *Nicholson's Journal* (dated February 1805) that he was the discoverer of palladium and the author of the anonymous advertisement. To celebrate the triple jubilee of Wollaston's announcement of the discovery of palladium, the Institution of Metallurgists is organizing an exhibition of the platinum metals at Grosvenor House, Park Lane, London, W.1, in the week beginning October 19. This exhibition, which will be opened by H.R.H. the Duke of Edinburgh, will illustrate the history of the platinum metals during the past 150 years, the great part they have played in the development of the chemical and electrical industries, and their modern scientific, technical and æsthetic uses. The exhibition will be open free to the general public during October 22–24 between the hours of 10 a.m. and 8 p.m.

Wollaston is now rightly regarded as the greatest pioneer in the platinum metal industry, since he was the first to bring a trained analytical mind to the problem of obtaining malleable platinum. The first account of the existence of platinum in the New World was published by Don Antonio de Ulloa in 1748, and the metal was first recognized as a new element by the Swedish assayer, Scheffer, in November 1751. In the following fifty years many workers in Europe studied the new metal and endeavoured to bring it into a coherent malleable form. W. Lewis, A. S. Marggraf, C. von Sickingen and Delisle were among those who published important observations on the metal; but it was not until about 1786 that Pierre-François Chabaneau, working in Spain in collaboration with the brothers de Elhuyar, succeeded in solving this problem; the methods they used, however, remained a close secret until the early years of this century, when an account of them was discovered among some old archives in Seville.

Working independently in Great Britain, however, Richard Knight discovered "a new and expeditious process for rendering platinum malleable" which he published in the *Philosophical Magazine* in 1800. Whether this publication was the incentive which prompted Wollaston to turn his attention from medicine, in which he graduated at Cambridge, to the study of the platinum metals is not known with certainty; but the fact remains that in this year he abandoned his medical practice and devoted the greater part of his energies to investigating the platinum metals. At this time the refining of the native alluvial platinum grains from Colombia was based on purely empirical observations. Wollaston, however, set himself the task of studying the chemical procedures of refining in a scientific manner, and the first fruits of this work were the discovery of palladium and rhodium. Almost simultaneously his friend, Smithson Tennant, working in Cambridge, discovered iridium and osmium and published his work in 1804. It was not, however, for another forty years that the Russian, Karl Klaus, working at the University of Dorpat, found the last of the platinum group of metals, ruthenium, in the osmiridium residue remaining after the aqua regia extraction of Russian platinum mineral. Ruthenium occurs only in very small proportions in Colombian platinum mineral, and this fact probably explains why it was not detected by Wollaston or Tennant.

Wollaston thus may be said to have been the first to undertake a systematic investigation of the complex problems involved in the refining and fabrication of the platinum metals. Not only did he succeed in devising scientific methods for their purification, but he also worked out procedures for the consolidation of platinum sponge into ingots of consistently high quality, and for many years carried on a profitable business in supplying platinum ware for use in the laboratory and in the concentration of sulphuric acid. The details of his methods of fabrication were kept secret until 1828, when he revealed them in the Bakerian Lecture to the Royal Society only about a month before his death on December 22.

By this time the beginnings of the present large platinum industry may be said to have been laid. In Britain, Percival Norton Johnson, assisted by his brother-in-law, Thomas Cock, had undertaken the business of platinum refining and fabrication which is now carried out by the firm of Johnson, Matthey and Co., Ltd. In Russia, the discovery of platinum in the Urals in 1819 was followed by the setting up of a platinum refinery at St. Petersburg under the direction of P. A. Sobolevsky. In France, Bréant and Couturier started work in 1812 and had a very flourishing business in supplying platinum ware to Western Europe between 1820 and 1837; they were succeeded by Desmoutis, who was joined by Quennessen about fifteen years later. In Germany, the great Heraeus business was founded in 1851, and the Deutsche Gold und Silber Scheide-Anstalt in 1873 under the name of Roessler.

In the past hundred years or so, the major uses of platinum and the platinum metals have been based on the high melting point and general chemical inertness of the metals. Platinum crucibles for chemical laboratory work were in demand from a very early date; much of the Spanish output made under the direction of Chabaneau went to make platinum apparatus for the great European chemists, and the work of meeting this demand was carried on by Wollaston, and later by Bréant and Couturier. Platinum began to be used for making jewellery in the eighteenth century, the work of the French goldsmith Janety being especially famous. Undoubtedly the first use of platinum on a large scale was for coinage; between 1828 and 1846 nearly half a million ounces of platinum were coined in Russia as 3-, 6- and 12-rouble pieces, and this currency was withdrawn only because a serious fall in the price of platinum caused fears of extensive counterfeiting.

The first use of platinum in the chemical industry was for making boilers for concentrating the dilute sulphuric acid made by the lead-chamber process; for this purpose Wollaston fabricated, between 1805 and 1818, no less than sixteen large boilers each weighing between 322 and 477 oz. Even to-day platinum boilers are in use for the preparation of the purest concentrated acid for analytical purposes. Probably the next important industrial use of platinum was as a catalyst, supported on magnesium sulphate or asbestos, for the manufacture of sulphuric acid by the contact process; vanadium catalysts have, however, largely supplanted platinum for this purpose owing to their lower price and inertness towards impurities which poison the platinum, but platinized silica gel is still used in some contact acid plants where a high quality of acid is required and relatively pure sulphur dioxide is available.

To-day platinum and platinum alloys are extensively used for melting high-grade optical glass and for making fibre glass, for precious metal thermocouples for the measurement of high temperatures, for electrodes for making persulphates for the manufacture of hydrogen peroxide, and for spinnerets for the production of artificial fibres. The electrical industry, too, is a very large user of the platinum metals in the form of contacts of all kinds, and as resistors for electric furnaces for operating above 1,000° C.

The catalytic properties of the platinum metals are also being exploited more extensively. Platinum and platinum–rhodium alloy gauzes are exclusively used for the manufacture of nitric acid by the ammonia oxidation process of Ostwald, and only recently it has been discovered that platinum dispersed on an alumina, silica or a silica–alumina base can be used in the vapour phase re-forming of the lighter petroleum fractions to produce high-octane motor spirit with superior anti-knock properties. Palladium, too, is finding wide applications as a hydrogenation catalyst in numerous organic syntheses. Recent American work has shown that palladium deposited on alumina is a very active catalyst for the reduction of anthraquinone to the corresponding hydroquinone, which can then be oxidized with air back to the quinone with the formation of hydrogen peroxide, a reaction first developed in Germany during the recent war for the manufacture of hydrogen peroxide for *V*2 rockets.

Although the platinum metals, with the exception of osmium, are highly resistant to oxidation at room temperature, ruthenium, palladium, rhodium and iridium, even in the massive form, tarnish readily on heating to temperatures above 500–600° C.; but the last three become bright again at temperatures of the order of 1,100–1,200° C. owing to the volatilization or decomposition of the oxide; ruthenium, however, continues to oxidize with increasing rapidity with rise in temperature owing to the formation of the highly volatile tetroxide. Platinum alone of this group remains untarnished on heating in air up to its melting point; but nevertheless it appears to be oxidized at high temperatures in air with the formation of an unstable volatile oxide which decomposes to the metal at slightly lower temperatures; this is the cause of the bright spangles of platinum often seen on the refractory surfaces close to the platinum windings of small resistance furnaces which have been operated for long periods. That an oxidation process is the cause of this phenomenon is proved by the fact that no such volatilization occurs in a vacuum or in reducing or inert atmospheres, and if the refractory surface is kept fairly cool the platinum is deposited in a black form which contains several per cent of oxygen.

Russia and Colombia remained the chief sources of the platinum metals until about the period of the First World War, when the large increase in the output of nickel and copper from the Sudbury mines in Canada combined with improvements in the refining process resulted in large amounts of the platinum metals becoming available in the residues from the Mond process of refining nickel and, later, in the anode slimes from the electrolytic refining of the nickel and copper. The amount of the platinum metals produced from this source rapidly increased during the next decade until it reached an average of about 250,000 oz. per annum, at which figure it has remained.

In the middle 1920's large deposits of platinum ores were found in various parts of the Transvaal, principally in the Potgietersrust, Lydenburg and Rustenburg areas, but by about 1930 only the Rustenburg area remained as an active producer. The output from this area has risen steadily until it is now about as large as that from Canada. The Merensky reef, which surrounds the Bushveld igneous complex in the centre of the Transvaal, is the principal source of the platinum metals; here they occur chiefly in combination with sulphur, arsenic and antimony in a norite rock heavily impregnated with chromite and containing nickel and copper sulphide minerals. In addition to sperrylite (platinum diarsenide), first found in the Sudbury nickel ores, and laurite (ruthenium sulphide), the South African platinum ores contain the new minerals, cooperite (platinum monosulphide), braggite (platinum–palladium–nickel sulphide) and stibiopalladinite (palladium antimonide). The platinum metals occur in these ores roughly in the proportion: platinum 100, palladium 55, rhodium 6, ruthenium 13, iridium 1, osmium 1.

Small alluvial deposits of platinum were discovered in Abyssinia in the late 1920's and much larger deposits in the Goodnews Bay district of Alaska in 1936. The Alaskan alluvial concentrates are remarkable in that they contain a high proportion of iridosmine, which has an unusually high content of iridium and a low content of osmium (only about 10 per cent). The Tasmanian alluvial deposits of osmiridium are now practically worked out; but considerable quantities of osmiridium, associated with native platinum and laurite, are recovered from the heavy black sands which collect on the corduroy tables during the treatment of the gold banket ore from various mines in the Witwatersrand area of the Transvaal; the precious metal concentrates obtained from this source contain up to 20 per cent of ruthenium with 30–40 per cent of osmium and 25–30 per cent of iridium, but are practically free from rhodium.

UNCERTAINTY, EXPECTATION AND DECISION IN BUSINESS AFFAIRS

During the recent meeting of the British Association in Liverpool, Section F (Economics) held a symposium on "The Logic, Philosophy and Psychology of Business Decision-making under Uncertainty", the main focus for discussion being Prof. G. L. S. Shackle's book, "Expectation in Economics" (second edition; Cambridge University Press, 1952). A day and a half were given to the discussion. Prof. Shackle, and many other economists, feel that the process by which a business-man reaches a decision depends very little, if at all, upon the rational assessment of probabilities which orthodox theory in the past assumed. But, of course, once economic theory departs from mathematical probabilities it is committed to the exploration of processes in which complexity, subtlety and even mystery are the most evident features; and yet decisions are made, and in the mass these decisions show trends and patterns which suggest that they are not altogether unamenable to rational investigation. The decisions obviously bear some relation to the facts, but they also bear a relation to the temperamental characteristics of the business-men who make them. Perhaps the object of the symposium might be described as that of discovering a bridge between these two very different terrains.

The present report will indicate briefly how each of the speakers at the symposium interpreted his part of the discussion. Then the treatment of a number of common themes will be described. The contributors and their topics were as follows: Prof. W. B. Gallie (University College of North Staffordshire), uncertainty as a philosophical problem; Dr. D. J. O'Connor (University College of North Staffordshire), uncertainty as a philosophical problem; Dr. I. J. Good (London), the appropriate mathematical tools for describing and measuring uncertainty; Prof. G. P. Meredith (University of Leeds), methodological considerations in the study of human anticipation; Prof. C. F. Carter (Queen's University, Belfast), theories of expectations; Prof. B. R. Williams (University College of North Staffordshire), the impact of uncertainty analysis upon economic theory, illustrated from the theory of profit; Mr. A. D. Roy (Sidney Sussex College, Cambridge), the possibility of empirical testing of alternative theories of uncertainty; and Prof. G. L. S. Shackle (University of Liverpool), summing up of the discussion.

Prof. Gallie's paper was concerned with viewing Prof. Shackle's book in a perspective of scientific method, philosophy and sociology. He made the valuable point that, whereas philosophy has done much to systematize our views on moral wisdom, little or nothing has hitherto been done to systematize our accumulated prudential wisdom.

Dr. O'Connor, while accepting Shackle's concept of potential surprise, stressed the need for establishing a relation between this mental state and the objective credibility of the hypothesis under consideration. In his view the reliability of an expert judgment is "latent in the funded and assimilated experience of the expert". He opposed the assumption that there are features of human behaviour, individual and social, which are in principle unpredictable, but did not indicate how he would deal with those novel situations which form the basis of Shackle's renunciation of frequency as the factor determining credibility. This paper may be described as viewing Shackle's theory as a possible successor to the out-moded Hedonic calculus.

Dr. Good's paper was tolerant, shrewd and suggestive. It laid bare the numerous subtle and complex decisions which the mathematician must make in probability problems before he ever puts his symbols on paper, and he went behind these decisions again to the underlying theoretical and in some cases metaphysical assumptions to which the mathematician commits himself. Concerning the crucial relation between subjective degree of belief and numerical probability, Dr. Good opened out an important possibility in this remark: "The introduction of numerical probabilities does not imply that a degree of belief is always or even usually at all precise". This clearly suggests that a useful correlation may be established between a discontinuou series of degrees of belief and a continuous series o numerical probabilities. The paper stressed the importance of constructing axiomatic systems in this field, and indicated the diversity of practical applications of such systems.

In the next paper, Prof. Meredith discussed Shackle's function $\varphi(x,y)$ as an essentially psychological concept, and indicated the experimenta problems in its empirical validation. Shackle's variables φ, x and y must be regarded as scales to be calibrated by experimental means. The variables may be discontinuous quantities, in which case Shackle's use of the differential calculus would be inappropriate. There may be several qualitatively different varieties of probability, and a probability may in many cases not be capable in principle o being expressed by a single number, but rather by a pattern of propositions, "the pattern of evidence o rational likelihood". Prof. Meredith's paper wa illustrated by a model constructed to facilitate th discussion of Shackle's φ function (see Fig. 1). In this model x represents values of the various possibl outcomes of a business venture ($x = -x$ represent losses). y represents the 'degree of belief, measured inversely as potential surprise' which the individual attaches to the various outcomes. φ, orthogonal to the x,y plane, represents the mental stimulus o 'interest' afforded by the various pairs of x,y values At 0, and for a certain 'inner range', zero surprise is attached to small gains and losses. Maximum surprise, or 'impossibility', $\bar{y}$, is attached to very hig gains and losses. The basin-shaped curve represent the impact of the business venture on the mind o the enterpriser and reaches maximum φ-value at two points—the 'focus-outcomes', representin maximum stimulus and deterrence, and determining the decision made; these are, in general, at intermediate values of x and y. The contours of th surface are characteristic of the individual's temperament. The continuous surface of this model implies continuous variables.

Prof. Carter explored the implication of discarding the continuous variables in Shackle's theory, and replacing them by discontinuous steps. Numerica measures must then be replaced by rankings. This raises a fundamental difficulty for Shackle's mode since "It is a logical impossibility to devise a means of compounding two pure rankings (or one ranking and a numerical index) to make another uniqu ranking". Prof. Carter demonstrated by a series o examples the novel kind of reasoning to which such an assumption would commit us.

Prof. Williams cast his net both wide and deep i the fundamentals of economic theory. He contraste static theory with its assumption of equilibrium conditions as a basis for rational decisions at the price of unreality, with dynamic theory with its implications of change and uncertainty, and its nee for theories of probability. The economist's habit o making psychological assumptions carries with it the need for consulting psychologists and sociologists He welcomed Shackle's theory as an attempt t provide a new conceptual framework of "expectational dynamics". The rest of the paper was a inevitably somewhat technical discussion of th impact of expectational dynamics upon Keynesia theory with particular reference to profit. Pro Williams closed with a plea for a sociological analys of the goals of business firms and organization within the socio-political system.

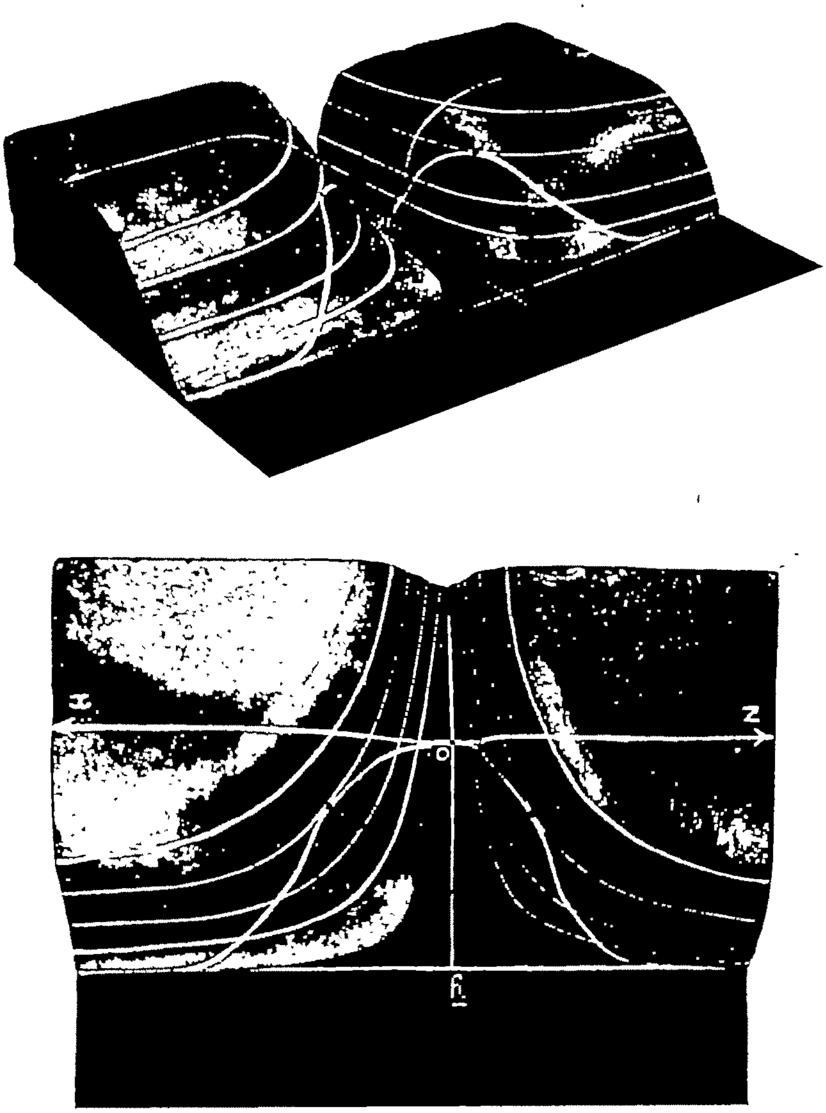

Fig. 1. Model of the Shackle function φ(x,y)

Mr. Roy attempted in his paper to specify actual methods by which different theories of uncertainty might be empirically tested. The link between past events and future outcomes is too tenuous and varied to allow of the elimination of what methodologists call the "intervening variables" of motive and expectation, but how can different theories of expectation be tested ? The first suggestion would be a statistical analysis of economic time series. The second would be by laboratory experiments on individuals placed in situations which mimicked as far as possible those confronting the typical business-man. Neither of these is promising. Mr. Roy recommended the compilation of individual case-studies of decision-takers in action by a research worker living in constant daily touch with the business-man, and having access to all the necessary information and business text-books to throw light on the latter's decisions. Mr. Roy indicated the methodological difficulties in the use of such data for discriminating between alternative theories of uncertainty.

Prof. G. L. S. Shackle surveyed the discussion, and has prepared the following statement relating to his comments: If we understood how decisions are made, we should understand how history is made. So far as this is true, it is rather obvious. Yet decision-making, the focal creative psychic event where knowledge, thought, feeling and imagination are fused into action, seems to have received only the most casual glances of scientific men and other scholars. Mathematics has shown in probability theory how to derive knowledge concerning aggregates of future events from aggregates of past events, but this technique is irrelevant to personally unique and crucial occasions of decision by an individual. Frequency-ratios are knowledge and have nothing to do with uncertainty. The individual can choose only between imagined and not between realized experiences, for when an experience is actually proceeding it is too late to choose something else. Thus decision must, it seems, be guided or determined by the thrust of imagined and anticipated enjoyments and distresses.

The relevant, legitimate and useful question for a person to ask himself, when his decision on this course of action, rather than that, will swing the whole evolution of his affairs into a different path, is not : How can I add together all the rival, mutually exclusive hypothetical outcomes of this course of action ? for the result of such addition would be meaningless ; and the question is not : What *will* be the result of this course of action ? for that cannot be known. The question is : What is the most exciting result that I can imagine this course of action as capable of producing, and again, what is the most alarming result ? ; where excitement and alarm each depend on two matters, the face-value of any hypothetical outcome in question, and its plausibility ; and if we are to consider a hypothesis *by itself*, the measure of plausibility must be something radically and essentially different from numerical probability, which depends for its meaning and existence on the viewing of hypotheses in their gregarious collectivity. By a line of thought which is too long to reproduce here, I have been led to invert the problem and adopt a measure of *disbelief* instead of a measure of positive confidence. The consequences are far-reaching.

If the line of ideas, the general direction only of which I have space to indicate, is to lead beyond a mere theoretical construction and make a solid contribution to knowledge, the interest and effort of philosophers, logicians, mathematicians, psychologists and economists will be needed for the intensive exploration of a territory the outlines of which were so brilliantly mapped by the seven contributors to the symposium at Liverpool.

So much for the distinctive features of the individual contributions. The following concepts and themes recurred in a number of the papers, and these suggest the movement of thought from which new developments in expectation theory may emerge.

Dissatisfaction with the frequency theory of probability. Decisions have often to be made concerning novel and unrepeated ventures. To these any frequency measure of probability is inapplicable; but even where it is theoretically applicable, there is a growing disbelief in the facile assumption that business decisions are based upon it.

The realization of the need for greater psychological realism on the part of economists. In a world in which the irrationality of man is everywhere manifest, it does seem somewhat naïve to assume that the business-man, of all people, is gifted with some unique degree of rationality which would give a mathematical sanction to his daily business decisions. It should, however, be pointed out that the word 'rational' itself demands some scrutiny. It is used to mean either 'effective' or 'ratiocinative'. There is a sort of practical rationality, or expertise, which depends upon years of experience rather than upon ratiocination. It is this which gives some measure of cogency to the degree of belief which the expert accords to the particular proposition.

The magnitude of the methodological problem. This is multifarious, and includes the relations between the social and the individual, conception and action, continuity and discontinuity, single and multiple causation, and a host of other relations.

The bearing of causative contexts and conceptual frameworks. The isolated business decision is probably a fiction. Decision arises out of the conceptual framework of the individual, and takes place within his socio-economic context.

The role of the conceptual model in theory-making. Theory attempts to simplify and clarify the welter of facts. It can do this only by setting up relatively self-contained abstract models; such a model, if it is to survive, must possess three features: internal consistency, as determined by logical analysis; validity, as determined by empirical tests; and power, as determined by its utility in both clarification and prediction.

The problem of quantification. This is an aspect of the validity problem, for in comparing empirical data with predicted outcomes there is a direct comparison of quantities. The theory of measurement is far from complete; even the physicists have their problems of metrology. Psychometrics and econometrics present problems of even greater complexity, but these are a challenge rather than a ground for pessimism.

A growing need for an adequate calculus of discrete quantities (as against the calculus of the arithmetical continuum). This may not be difficult for the pure mathematicians, but the users of mathematics would need to acquire new habits of thought, as well as new modes of calculation. The landscape model of Shackle's function in the accompanying illustration would have to make way for a model of steps and movable platforms.

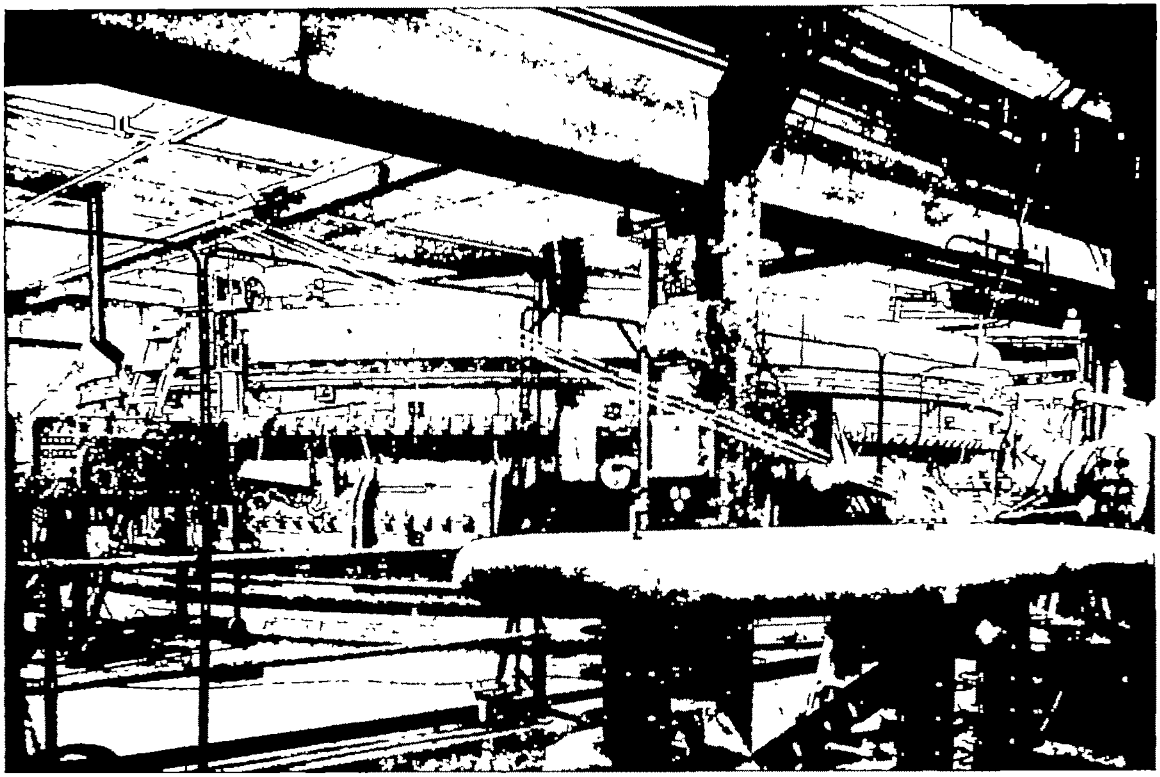
G. P. MEREDITH

PROTON SYNCHROTRON OF THE UNIVERSITY OF BIRMINGHAM

THE proton synchrotron in the Physics Department of the University of Birmingham is now able to accelerate particles to an energy of 1,000 MeV.; it first operated at full energy on July 16. A greater energy than this is known to have been reached artificially only in the United States, where the Brookhaven 'Cosmotron'[1] gives protons of an energy of 2,300 MeV. These two machines, together with a rather larger proton synchrotron approaching completion at Berkeley, California, are designed to provide experimental facilities for nuclear physics in an energy range above that which is economic for synchro-cyclotrons. Future proton synchrotrons, planned to incorporate the new strong focusing principle, will probably extend the energy scale considerably further.

The Birmingham synchrotron has been developed from the original proposals of Oliphant, Gooden and Hide[2], whose aim to reach a proton energy of about 1,000 MeV. was, just after the Second World War, ambitious but not unreasonable. Detailed design began in 1946 with the aid of a grant from the Nuffield Foundation, and construction started in 1947. The project was under the guidance of Prof. M. L. Oliphant until he left the laboratory in 1950, and, since then, responsibility for the development and testing of the machine has been in the hands of the present head of the Department, Prof. P. B. Moon. The undertaking has been financed mainly by the Department of Scientific and Industrial Research, without the support of which the project could scarcely have been undertaken by a university department. Several large and important parts of the equipment, such as the motor-generator, vacuum sections and high-tension generator, were supplied by outside firms; but the main technical responsibility has been undertaken throughout by the Department of Physics, and much of the actual construction was provided by the departmental workshops. The very considerable technical effort necessary has been supplied over six years by a large number of physicists and assistants, many of whom are no longer in the laboratory to witness the successful outcome of their work.

The first notable feature of the Birmingham synchrotron is its size. This is not shown to advantage in the accompanying photograph, since the machine had to be built within the fairly small space available in the Nuffield Research Laboratory, which was designed for (and still houses) the University 60-in. cyclotron[3]. The illustration gives a general view of the magnet (810 tons), which is built of C-shaped steel laminations ¼ in. thick, arranged in a circle with the annular gap outwards. The diameter of the mean horizontal orbit in which the protons circulate is 900 cm., and the magnetic field necessary to keep a proton of an energy of 1,000 MeV. moving in an orbit of this size is 12,500 gauss. Power for the magnet is supplied by a motor-generator set developing



General view of the proton synchrotron of the University of Birmingham, showing magnet, vacuum system, radio-frequency power amplifier and injection apparatus

1,100 V. which is connected to the air-cooled coils of the magnet at the beginning of the magnetic cycle. The magnet has an inductance of 0·1 H. and a resistance of 0·01 ohm, and a peak current of 12,500 amp. (corresponding to a field of 12,500 gauss in the magnet gap) builds up in the coils in 1 sec. The field excitation of the generator is reversed to limit the peak current and to reduce the current quickly to zero; when the current has passed its peak, most of the energy stored in the magnet feeds back into the motor generator, which has on its shaft a 36-ton flywheel for energy storage. The magnetic field-cycle repeats every 10 sec.

The magnet gap is 21 cm. high and contains a sectionalized porcelain vacuum tube of internal dimensions 10 cm. by 36 cm.; a pressure of 8 × 10^{-7} mm. is maintained by five diffusion pumps each with a speed of 2,000 l./sec. through a water-cooled baffle. A pulse of protons is shot tangentially into the vacuum system from a Cockcroft–Walton high-tension generator just after the magnetic field begins to rise. The injection energy is 460 keV., and the protons begin to move in a magnetic field which for this energy gives their path a radius of about 450 cm. On their way around the vacuum system the particles pass through an accelerating electrode ('cee') to which a radio-frequency voltage is applied; for each revolution the proton energy may be thus increased on the average by about 200 eV. This energy increment is just that required to maintain the particles in the mean orbit as the magnetic field rises. There must, of course, be synchronism between the applied radio-frequency voltage and the circulating protons, and as the particles speed up the applied frequency is increased. The frequency-range necessary for the acceleration period of 1 sec. is 330 kc./s. to 9·3 Mc./s., and during this time the protons make about 5 × 10^{6} revolutions in or near the mean stable orbit. The necessary radio-frequency voltage on the accelerating electrode is achieved over a 30/1 frequency range by roughly tuning the 'cee' capacitance. This is done by a mechanically variable inductance driven in accordance with the known frequency-time variation. The form of the frequency-time law was found from precise measurements of the rate of rise of magnetic field which has been found satisfactorily reproducible. The radio-frequency is generated as a beat between a fixed oscillator and a variable oscillator the frequency of which is governed by a mechanically driven condenser shaped to provide the correct time-variation. Further details of the whole equipment were given in an earlier article[4].

In preliminary tests of the synchrotron, beams of particles were observed to strike current collection and scintillation probes inserted at various points in the vacuum tube. For testing over the full range of energy, a convenient form of beam indication is the signal induced on an insulated plate at the bottom of the vacuum system by the bunched beam circulating near the median plane. From the size of this signal, it is estimated that the fully accelerated pulses contain about 10^{8} protons. At the conclusion of the acceleration, the beam may be made to move either to the inside or to the outside wall of the vacuum tube; provision is being made for the insertion of suitable targets. Scattered protons have been observed outside the vacuum system, and tracks of π-mesons have been seen in nuclear emulsions exposed near by.

In the present early stages of operation of the synchrotron, effort is concentrated mainly on improving the performance and on measuring radiation levels. This is necessary for the proper design of shielding which will protect those working near the machine and also allow access to the various beams of radiation from targets. A detailed experimental programme is being prepared, and it is hoped that this synchrotron, which provides π-mesons of energies up to at least 700 MeV., will add significantly to existing information on the nuclear interactions of high-energy particles. It is clear that the accumulation of events of interest in nuclear emulsions and cloud chambers is likely to be rapid.

OBITUARIES

Prof. A. F. Holleman

Arnold Frederik Holleman died on August 11, and so passed the doyen of Dutch chemists and one who held a special place in the hearts of his countrymen, not only for what he had done for the cause of science, and of organic chemistry in particular, in Holland, but also as one of the band of famous scientists who succeeded in bringing the universities of Holland into the very forefront of scientific progress.

During his long life of almost ninety-four years, Holleman formed a connecting link between the earlier period of organic chemistry and modern developments. He was born at Oisterwijk in North Brabant on August 28, 1859, and received his early chemical education from Dr. Lamers, a pupil of Kekulé. He proceeded in 1879 to Leyden, where he studied under the two famous teachers, Franchimont and van Bemmelen, and also had instruction from van Romburgh, Bakhuis Roozeboom and Lobry de Bruyn. Then followed a period under Bunsen at Heidelberg and one in von Baeyer's laboratory at Munich, where he was contemporary with Bamberger, Claisen, Nef and Friedlander. In 1887 he returned to Holland to work with van't Hoff at Amsterdam, where he also met Eijkman. Here he started his career as a teacher; he became professor at Groningen in 1893, and a little later he succeeded Lobry de Bruyn at Amsterdam, where he remained until he retired in 1924 at the age of sixty-five.

The effect of Holleman's lifelong friendship with van't Hoff and his contacts with Eijkman and Bakhuis Roozeboom is to be seen in the direction his researches took at Groningen and Amsterdam. As a student of the Leyden school, he was interested in the chemistry of substitution in aromatic compounds, and his thesis for his doctorate (1887) dealt with "Researches on the so-called β-Nitro-cymene"; his fame, however, rests on the application of exact physico-chemical methods to the quantitative study of the problem. His researches enabled him in 1910 to publish his famous book "Die Einführung von Substituenten in den Benzolkern", truly the basis on which the English school later built the electronic theory. He was still stressing the importance of the quantitative aspect of the subject in probably the last of his papers, published in 1947.

After his retirement, Holleman lived in Bloemendaal, but still devoted himself to science, as secretary to the Hollandsche Maatschappij der Wetenschappen, Haarlem, and on various committees of the Dutch Chemical Society, which obtained its Royal title a few days before his death, and in which he was particularly interested.

No notice would be complete without reference to Holleman's fame as a teacher. Anyone who studied organic chemistry at a Dutch university could 'feel' it, and it was also a reason for the success of his text-book, which passed through sixteen editions between 1896 and 1951 (he supervised the whole of the manuscript of a recent English translation) and was translated into many languages. S. Coffey

We regret to announce the following deaths:

Mr. R. H. Burne, F.R.S., sometime physiological curator of the Hunterian Museum, Royal College of Surgeons, on October 9, aged eighty-five.

Mr. James Fairgrieve, formerly reader in education with special reference to geography in the Institute of Education, University of London, on October 8, aged eighty-three.

NEWS and VIEWS

Aerodynamics at the National Physical Laboratory: Mr. A. Fage, C.B.E., F.R.S.

Mr. A. Fage, who retired from the post of superintendent of the Aerodynamics Division of the National Physical Laboratory last summer, is one of the pioneers of aeronautical research. He went to the Laboratory in 1912, after an education at the Portsmouth Dockyard Schools and the Royal College of Science, London, and joined the small group of workers who were beginning to establish an aeronautical section at the Laboratory under the guidance of the then Dr. Stanton and Mr. Bairstow. His early work ranged over the whole field of aerodynamics as it then existed; but he made a special study of the characteristics of airscrews and laid the foundations of airscrew theory. He wrote two books at this time, on airscrews and on the aeroplane, as a guide to designers. About 1920, Mr. Fage began to study the problems of the boundary layer and of turbulent airflow which have been his main work and have brought him international fame and the fellowship of the Royal Society (1942). He was the first to measure, by the use of Stanton's surface Pitot tube, the distribution of skin friction along the chord of an aerofoil, and to show in detail the nature of the transition from laminar to turbulent flow. His work on the effects of surface imperfections on skin friction did much to emphasize the great importance of smooth and accurately shaped surfaces for the attainment of the lowest possible drag.

Mr. Fage was a brilliant experimentalist but had a sufficient knowledge of the underlying theory to enable him to interpret lucidly the results of his experiments. Many of his experimental researches show an almost uncanny skill, and also a great degree of patience, in attacking new and difficult problems. Incidentally, he made some of the first experiments on laminar flow aerofoils. He was appointed superintendent of the Aerodynamics Division at Teddington in 1946 and since then has devoted much of his time to the improvement and modernization of the equipment of the Division, particularly the planning of the great extension of high-speed researches now in progress. His work will long be remembered and honoured, especially in the field of experimental research on fluid motion, of which he was a master. He was awarded the C.B.E. in the Coronation honours as a recognition of his great contributions to aeronautical knowledge.

Dr. W. P. Jones

Dr. W. P. Jones, who has succeeded Mr. Fage, went to the National Physical Laboratory in 1933, having taken degrees in both mathematics and physics. His mathematical ability led to his being attached to the group of scientists under Dr. R. A. Frazer who were engaged on flutter research, and he has made this subject his chief work at the Laboratory ever since. In particular, he has studied profoundly the theory of aerodynamic forces on bodies in unsteady motion, and is an acknowledged world authority on this subject. His work on the aerodynamic derivatives of oscillating aerofoils has provided an invaluable basis for the solution of flutter problems, and his methods are widely used by aircraft designers. Having established a satisfactory theory for low speeds, he proceeded to study the effects of compressibility of the air, and so extended his theory into the transonic and supersonic ranges of flight. His findings have been compared with experimental measurements whenever possible, with good results, and it can be said that as a result of his work we now possess a very substantial foundation of knowledge of flutter derivatives, except in the narrow range of speeds close to that of sound.

Dr. Jones has, from time to time, devoted his attention to other problems, usually related to fluid motion, and has written a large number of papers for the Aeronautical Research Council and its committees, many of which are published in the Reports and Memoranda of the Council. His interests outside aeronautics are gardening and shooting, for which latter recreation he likes to go to his native Wales. As superintendent of the Aerodynamics Division at Teddington he will naturally have less time for individual research; but it is to be hoped that he will find some opportunity of extending his work on unsteady fluid motion, and particularly of studying further the difficult but important question of flutter in the transonic speed-range.

Recruitment of Higher Personnel for the British Textile Industry

In his address to the autumn convocation of the Textile Institute, Manchester, on October 2, Sir E. Raymond Street, chairman of the Cotton Board, Manchester, and former president of the Institute, stressed the need for the British textile industry to employ more highly trained staff, not only technologists but also men expert in management and its various techniques and who possess character and energy. He thought that there is much to be said for the practice of employing at least one person whose duties might not be rigidly defined but who has the ability and training to fill a sudden vacancy among the senior staff or who could examine a technical or managerial problem. Industry needs to attract more of the best brains in the country which have traditionally entered the professions or the Civil Service; it can no longer rely entirely on traditional methods of recruitment. A definite policy of staff recruitment and promotion is required, and this must take account of the fact that the widening of educational opportunities, with the consequence that more and more of the ablest boys enter the grammar schools and then the technical colleges and universities, greatly diminishes the possibilities of finding the requisite ability for promotion on the shop floor. To attract more of the best material into industry it is not sufficient to make the needs of the textile industry known. Within the industry, and within individual firms, an organization should be created for the reception and training of staff, and this should include provision for training in the techniques of management. Sir Raymond ended by saying that the textile industry is probably a little too cautious in giving its young men responsibility, and experience could only come through responsibility.

Irregularities in the Period of Rotation of the Earth

An examination of all the possible factors contributing to variations in the earth's rotation period has been made by Walter Munk and Roger Revelle and published by them in a paper entitled "On the Geophysical Interpretation of Irregularities in the Rotation of the Earth" (*Mon. Not. Roy. Astro. Soc., Geophys. Supp.*, 6, 6; Sept. 1952). It is shown that the seasonal variation in the distribution of air mass has a very small effect and that alterations in the sea-level cannot account for the major variations in the length of the day, although the effect is not necessarily negligible. If random fluctuations in the elevation of continental blocks of the earth's crust were sufficiently large to cause observed changes in the length of the day, they would also cause displacements in the pole of rotation much greater than those observed from 1890 to 1950. The evidence from tide gauges suggests that oscillations in the elevation of crustal blocks have been less than ten per cent of the amount required to account for the observed fluctuations in the length of the day. It is suggested that electromagnetic coupling of the mantle to a turbulent core could account for the observed fluctuations if the conductivity of the mantle is about 10^{-9} e.m.u. A numerical relationship has been derived between the fluctuations in the length of the day—as measured from observatories anchored to the mantle—and the variations in the westward drift of the earth's magnetic field, and this indicates that these fluctuations can be explained by a variable motion in the core amounting to a fraction of the total motion.

Science and the Arts

In an article comparing the relative merits of the arts and sciences, Prof. R. E. Gibson, professor of chemistry and director of the Applied Research Laboratory at the Johns Hopkins University, traces the development of applied research as it has evolved from natural philosophy and suggests that pure research is in danger of being smothered by its aggressive and powerful offspring (*Amer. Sci.*, **41**, No. 3; July 1953). Gibson believes that modern science reflects the dual nature of man and that both the useful and liberal arts are manifestations of the passion for truth that underlies civilization. In the same journal the ultimate disposal of radioactive wastes is discussed by Mr. L. P. Hatch, who describes the use of montmorillonite clay as a method of packaging radioactive waste which is now being investigated at the Brookhaven National Laboratory.

Other articles include one by Dr. Shields Warren on the contribution of atomic energy to health.

"The Changing Flora of Britain"

UNDER the above title, and under the general editorship of J. E. Lousley, the papers read at the third conference arranged by the Botanical Society of the British Isles in 1952 have now been made available in book form (obtainable from the Society, c/o Department of Botany, The University, Oxford; price 15s.). This unusually full and interesting conference has already been noticed at some length in *Nature* (169, 1076; 1952). Readers of the book will find that it contains much original information and thought on floristic topics by distinguished exponents. The several essays, some twenty-four in all, deal with the central theme in its many aspects, the evidence being drawn from ecology, palæobotany, phytogeography and relating to such topics as the introduction and spread of aliens, special studies of trees and shrubs, etc. The wide casting of the net is perhaps indicated by the inclusion of such papers as those on "A Zoologist's Approach to a Changing Flora", "The North American and Lusitanian Elements in the Flora of the British Isles", and "The Conservation of British Vegetation and Species". This conference, together with the valuable text that has emerged from it, should do much to stimulate new interest in British field botany.

Wall Structure in *Valonia*

IN an investigation of the cell-walls of species of *Valonia* and *Dictyosphaeria*, using the electron microscope, a general similarity of structure and development has been demonstrated (F. C. Steward and K. Mühlethaler, *Ann. Bot.*, N.S., 17, 66, 296; 1953). The first cellulose laid down at a new surface, as on aplanospores, consists of a tangle of randomly arranged fibrils, these being embedded in a pectin-like amorphous material. As this first cellulose layer is either unable to grow enough by plastic flow or to stretch elastically, it is eventually torn and a new layer is formed within. At first the strands of the new layers are not exactly parallel, but they eventually acquire a high degree of regularity. In successive lamellæ the fibril direction shifts abruptly, apparently through an angle of 120°, that is, the direction is repeated every fourth layer. The bearing of these observations on the interpretation of the growth of the cell wall is considered.

International Institute of Refrigeration

COMMISSIONS I and II of the International Institute of Refrigeration held a joint meeting at Zurich during September 10–12. The main topics of discussion were: (1) liquefaction, distillation, rectification and adsorption; (2) properties of materials used at low temperatures. Prof. P. Grassmann was in charge of the local arrangements, which included visits to the laboratories of the University and to heat pump installations. A survey of the field of work of Commission I was given by Prof. F. E. Simon (Oxford) and that of Commission II by Dr. Ezer Griffiths (National Physical Laboratory, Teddington). The contributions on gas liquefaction, etc., included papers on liquid vapour equilibrium of the system argon–oxygen and the manufacture and use of tonnage oxygen. On the engineering side, apparatus for the liquefaction of air, hydrogen and helium was discussed. A group of papers was submitted on properties of materials: one dealing with the effect of low temperatures on the engineering properties of metals, another on the metallurgy of iron and steel at − 196° C., and a paper on the strength of aluminium crystals at low temperatures. Another group covered thermal conductivities of metals, moist cork, and porous materials under reduced pressures. Altogether nineteen papers were read and discussed. A bulletin containing the papers and discussions will be published by the Institut International du Froid, 177 Boulevard Malesherbes, Paris 17e.

Zoological Society of London: Special Courses

THE Zoological Society of London, at the request of the Colonial Office, arranged a study-leave course during the month of September for selected members of the Colonial Service in Africa; those attending came from game, veterinary and forestry departments. The course was designed to help the members of those services who wish to do some serious work on the African fauna, particularly the mammals, but need some assistance and guidance in setting their steps in the right direction. The course consisted of lectures, demonstrations and practical work; it included instruction on elementary anatomy and physiology, reproductive cycles, parasites, classification, ecology and the techniques of field-work. Prof. E. C. Amoroso (Royal Veterinary College) and Mr. R. W. Hayman (British Museum (Natural History)) collaborated with the Society's staff: it is hoped that similar courses will be arranged in future years.

A course for school teachers has been provided, in conjunction with the L.C.C. Education Department, on "Animals at the Zoological Gardens". Lectures are given on Saturday mornings during October and November; after each lecture the class divides into small parties that are conducted by the lecturers around special sections of the menagerie for demonstration and further informal instruction. The course is designed as an aid to teachers who bring parties of children on educational visits to the Zoological Gardens, so that they may organize their work to the greatest possible advantage. Prof. H. R. Hewer, assisted by Dr. K. A. Kermack and Dr. D. M. Ross, is conducting the course. The Society is arranging its usual lectures for children of Fellows during the Christmas holidays.

Fifth Canadian High Polymer Forum, London, Ontario

THE fifth Canadian High Polymer Forum will be held in the auditorium of the London Public Library and Museum, Queen's Avenue, London, Ontario, during November 19–20. Seventeen papers have been arranged, and further contributions can still be accepted for the final programme by submitting a title and an abstract of two hundred words to the programme chairman, Prof. R. V. V. Nicholls, McGill University, Montreal, Quebec. Besides visits to the University of Western Ontario and to local industries, there will be a special dinner at which Dr. D. P. Riley, of the Royal Institution, London, England, will give an address. Hotel reservations and further information can be obtained from the secretary-treasurer of the Forum, Dr. H. Leverne Williams, Polymer Corporation, Ltd., Sarnia, Ontario.

Nature Conservancy: Awards

THE Nature Conservancy has made the following awards of research studentships for postgraduate training in ecology, tenable for periods of up to three years at the universities shown: *Botany*, Miss J. C.

Brown and G. W. F. Sewell (Royal Holloway College, London); *Zoology*, J. K. Bates (Jesus College, Oxford), P. F. Entwistle (Imperial College of Science and Technology, London), T. Huxley (Balliol College, Oxford), C. J. Duncan and E. J. Perkins (Queen Mary College, London), P. E. S. Whalley (University College of North Wales, Bangor), J. Godfrey (University of Edinburgh) and Miss L. M. C. McCartan (St. Hugh's College, Oxford); *Physiography*, C. Embleton (St. John's College, Cambridge) and W. A. Westgate (University of Durham).

Illuminating Engineering Society: Awards

The Illuminating Engineering Society has announced the following awards in connexion with papers presented to the Society during the past year: *Leon Gaster Memorial Premium*, to W. D. Chesterman (Royal Naval Scientific Service) and J. B. Collins (now at the Building Research Station, Garston) for their joint paper on problems of underwater illumination; *Silver Jubilee Commemoration Award*, to J. R. Wakefield (University of Nottingham) for his paper on an investigation of glare in mine lighting, and in view of the number and standard of entries submitted this year, a second award to Miss P. M. Excell (Research Laboratories, British Thomson-Houston Co., Ltd.) for a paper on illuminating calculations for installations using long linear light sources.

University of Birmingham: Appointments

Prof. A. J. Murphy, professor of industrial metallurgy in the University of Birmingham, has been appointed director of the Combined Departments of Metallurgy in succession to the late Prof. D. Hanson. The title of University Research Fellow has been conferred upon the following during the tenure of their present posts: *Physics*, Dr. F. Aughtie (Department of Scientific and Industrial Research); *Electron Physics*, Dr. G. F. Alfrey (Admiralty contract). A. J. Williams has been appointed a Research Fellow in the Department of Metallurgy.

University College of North Staffordshire

Dr. F. W. Cope, reader and head of the Department of Geology, University College of North Staffordshire, has been appointed professor of geology. The Polymer Corporation, Ltd., Sarnia, Ontario, has founded a research studentship in chemistry in the College for the support of postgraduate research on cationic polymerization under the direction of Dr. P. H. Plesch. The Blythe Colour Works, Ltd., Cresswell, North Staffordshire, has founded a fellowship in chemistry for the support of fundamental investigations into inorganic colouring matters; the first holder of the fellowship is Dr. S. C. Nyburg, assistant lecturer in the Department of Chemistry.

British Society of Rheology: Officers

At the annual general meeting of the British Society of Rheology, held at the Imperial College of Science and Technology, London, on September 25, the following officers were elected: *President*, Dr. L. R. G. Treloar; *Honorary Secretary*, Dr. P. Feltham (Flat *H*12, Sloane Avenue Mansions, London, S.W.3); *Honorary Treasurer*, Mr. N. Wookey; *Honorary Editor*, Mr. A. A. Milne; *Northern Representative*, Mr. L. Grunberg; *Midland Representative*, Mr. A. W. Richardson; *Ordinary Members of Committee*, Mr. E. B. Atkinson, Mr. D. W. Jopling, Dr. E. W. J. Mardles and Mr. W. F. O. Pollett.

British Occupational Hygiene Society: Conference in London

The first conference of the British Occupational Hygiene Society will be held in the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1, on November 2, starting at 11 a.m. The conference, which is open to those who are not members of the Society on payment of a fee of 10*s*. 6*d*. (covering tea and a copy of the report), is designed to provide a common forum for the many professions, medical and non-medical, concerned with occupational hygiene. Sir Walter Monckton, Minister of Labour, will open the proceedings, and will be followed by the president of the Society, Dr. Thomas Bedford (director of the Environmental Hygiene Research Unit, Medical Research Council), who will give an address. The rest of the programme will consist of three papers, as follows: measuring the worker's environment, by S. A. Roach (dust physicist, Pneumoconiosis Research Unit, Medical Research Council); problems of chemical toxicity, by Dr. D. G. Harvey (head of the laboratories, Department for Research in Industrial Medicine, Medical Research Council); and occupational hygiene and the industrial designer, by J. E. Braham (engineering controller, Imperial Chemical Industries, Ltd.). Those who intend to be present at the conference should notify before October 15 the honorary secretary of the Society, Peter C. G. Isaac, Public Health Engineering Laboratory, King's College, Newcastle upon Tyne, from whom further particulars can be obtained.

Announcements

The Eddington Lecture will be given this year in Cambridge at the Arts' School, Bene't Street, Cambridge, on November 3 at 5.30 p.m. by Prof. H. H. Price, Wykeham professor of logic in the University of Oxford. The title of Prof. Price's lecture will be: "Some Aspects of the Conflict between Science and Religion".

The Leopold von Buch Medal of the German Geological Society has been awarded to Dr. W. J. Arkell, senior Research Fellow of Trinity College, Cambridge, particularly for his researches on the British Jurassic which have greatly stimulated work on the problems of Jurassic stratigraphy all over the world.

Dr. Laurence McKinley Gould, president of Carleton College, Northfield, Minnesota, who is well known as a geologist and geographer, has been appointed to the board of the United States National Science Foundation in succession to Dr. J. B. Conant, who has resigned on becoming the United States High Commissioner for Germany.

The Chemische Gesellschaft in der Deutschen Demokratischen Republik was founded in Berlin on May 11. The officers are: Prof. E. Thilo (*president*); Dipl.-Ing. Kaiser (*secretary*); Prof. H. Bertsch (Berlin); Prof. H. Franck (Berlin); Dr. Heyder (Bitterfeld); Dr. W. Schirmer (Leuna); Prof. A. Simon (Dresden); Prof. W. Treibs (Leipzig).

The Institute of Rural Life at Home and Overseas will hold its annual conference at High Leigh, Hoddesdon, Herts, during January 4–8 under the chairmanship of Sir John V. W. Shaw, formerly governor and commander-in-chief of Trinidad and Tobago. The conference will consist mainly of a number of lectures and discussion-group sessions. Further details can be obtained from the Secretary of the Institute at 84 Eccleston Square, London, S.W.1.

CHEMISTRY OF PLANT GROWTH SUBSTANCES

CHEMICAL structure in relation to plant growth-regulating activity was discussed at a symposium held in Sweden in the Botanical Department of the University of Lund during August 10–14. The meeting was arranged by Prof. H. Burström (Lund), Dr. H. Veldstra (Amsterdam) and Prof. R. L. Wain (London), and participation was restricted to active workers in this field. Some forty chemists and biologists from eight countries were present.

Dr. Veldstra, who introduced the first session on "Structure and Activity", gave a review of published work in this field and an account of his own recent investigations. In particular, he showed that compounds like 1-naphthylmethanesulphonic and 1-naphthalenesulphonic acids can show growth-regulating activity at higher concentrations (10^{-2}–10^{-3} *M*). In view of the high dissociation constants of these acids, it would appear that the anion is active in promoting the growth response. Dr. C. Hansch (Claremont, U.S.A.) discussed the evidence for the reaction of a growth substance with a plant substrate. His suggestions that, within the plant, a nuclear chlorine atom can be removed from certain chlorinated benzoic acids and that a methyl group might be eliminated, for example, from the growth substance 3-chloro-2 : 6-dimethylbenzoic acid, promoted a lively discussion. In assessing growth-regulating activity Dr. Hansch rates a compound as active if it promotes a 5 per cent increase in growth above the controls in the *Avena* cylinder test. This method of assessment was criticized as one in which synergism may play an important part. In the last paper of this session, Prof. H. Soding (Hamburg) discussed the chemical nature of the growth substance in *Avena* coleoptiles. In recent years Prof. Söding has made a survey of the data relating to the possible existence of auxins *a* and *b*, and a re-analysis of the evidence relating to acid and alkali stability and rates of diffusion has led him to conclude that, so far, indole compounds are the only auxins which have been established as occurring naturally within the plant.

The second session was devoted to papers on optical isomerism in relation to growth-regulating activity. Dr. H. Matell (Uppsala) described how he has determined configurations in a series of optically active aryloxyalkylcarboxylic acids by constructing melting-point curves. When the optical isomers of similar aryloxy acids are studied in this way, the curves reveal the formation of quasi-racemates when the two isomers differ in configuration. Dr. B. Åberg (Uppsala) followed with a paper on the physiological effects of these compounds. His results were in agreement with the idea that activity involves the association of the compound with some enzyme system, certain groupings in the molecule becoming associated with specific receptor groups on the enzyme surface. His work is closely in line with that of Prof. Wain, Prof. Burström and others, and in discussion it was evident that much work on anti-auxins and auxin antagonists is now proceeding. This field of investigation was considered further in the third session. Prof. L. J. Audus (London) gave a critical evaluation of the present concepts of auxin antagonists. He made a plea for rigid standardization in the preparation of biological materials and in experimental method, stressing the importance of proper statistical analysis of results. Dr. H. Erdtman (Stockholm) discussed some approaches to the study of anti-auxins, and Dr. C. Mentzer (Lyons) described his investigations on the antagonistic effects of *N*-methyl-*N*-phenylglycine and *N*-methyl-*N*-acetonylaniline on the growth of carrot in tissue culture experiments *in vitro*.

The fourth session, on the mode of action of growth substances, was opened by Prof. R. L. Wain (London), who discussed the breakdown of certain ω-aryl- and ω-aryloxy-alkylcarboxylic acids in plants. Chemical evidence was presented which indicates that, within the flax plant, phenoxy acids may be degraded by a β-oxidation mechanism and that with certain chain-lengths ω-oxidation might also occur. These findings were considered in relation to the results obtained by other workers in human and animal metabolism studies. Prof. Wain also indicated the steric considerations which led Toothill to prepare and test the growth-regulating activity of 2 : 4-dichloro-6-fluoro- and 2 : 4-dibromo-6-fluorophenoxyacetic acids. The high activity found with these compounds was shown to stand in marked contrast to the inactivity of the corresponding 2 : 4 : 6-trichloro- and 2 : 4 : 6-tribromo-acids. Certain physico-chemical aspects of plant growth-regulating activity were dealt with by Dr. R. C. Brian (Bracknell, Berks), who gave a paper on the interaction of growth substances with monolayers of proteins, lipids and material produced directly from plant tissues. Evidence was presented showing that 2-methyl-4-chlorophenoxyacetic acid is almost completely ionized at the *p*H occurring within plant cells, where it must therefore exist as the anion. The increase in physiological activity which is observed at lowered *p*H was attributed to ionization changes in the protein complexes within the plant affecting their interaction with the growth-substance anion. Material obtained from the tissues of different plant species was shown to vary greatly in capacity to adsorb the growth substance; but no general correlation between this capacity and susceptibility of the plant to the herbicidal action of the chemical could be drawn. Drs. H. Linser and K. Kaindl (Linz, Austria) discussed the concentration/activity curves of various growth activators and growth inhibitors in the "*Avena*-Pastentest" and the interpretation of the results. Dr. H. L. Booij (Leyden), in a theoretical contribution on mode of action, directed attention to the similarity between the action of plant growth substances and those of haptens in serological reactions. He pointed out that, in general, both types of compound are water-soluble, have low molecular weights and they may operate as anions. It was suggested that certain enzymes bound to protein within the resting plant cell might be liberated under the action of a growth substance in a manner analogous to that in which a hapten, by associating with a specific antibody, affects the normal antigen–antibody relationship.

The final session, dealing with physiological aspects, was opened by Prof. K. V. Thimann (Harvard), who described work with certain compounds which might arise from the oxidation of 3-indolylacetic acid. The inactivity of these substances has led him to consider it unlikely that an oxidation mechanism is involved in the growth-regulating activity of this acid. In his studies on anti-auxins, Prof. Thimann has found that, under certain conditions, 3-methylindole can depress the activity of 3-indolylacetic acid. The effect is not shown with low concentrations of the acid, indicating that competitive antagonism is not involved and that 3-methylindole is not an anti-auxin. Prof. Thimann has concluded from further experiments that 2 : 4-dichloroanisole, claimed to be an anti-auxin by Bonner, is likewise a growth inhibitor only. Studies with 3-indolylacetonitrile were also described by Prof. Thimann. Evidence was presented which indicates that, in tests where the nitrile shows activity, such activity depends upon its conversion to 3-indolylacetic acid within the plant tissue. Prof. H. Burström (Lund), in a comprehensive physiological paper, made an attempt to define growth activity. In particular, he dealt with auxin and anti-auxin activity, the type of antagonism shown only by external growth substances, the disturbance of geotropic responses, and toxicity. The paper, which was illustrated throughout by detailed reference to the growth effects obtained with specific compounds, focused attention on the complex interplay of physiological processes which may be concerned in promoting the various types of growth response.

R. L. Wain

CHEMICAL PROCESSES AND CHEMICAL ENGINEERING TECHNIQUES

The first chemical plant exhibition to be held in Great Britain since 1936 was housed at Olympia, London, during September 3–17 in conjunction with the annual engineering, marine and welding exhibitions. The Institution of Chemical Engineers, together with the Chemical Engineering Group of the Society of Chemical Industry, marked the occasion by holding a chemical engineering conference during the five days commencing September 7.

The meetings were avowedly general in nature, being designed to support the plant exhibition, and the theme of the entire conference could be described as one of 'materials and methods'. Perhaps the focal point of the meetings was that held under the chairmanship of Mr. Stanley Robson, at which the implications of recent reports upon American practice ("Chemical Apparatus in the U.S.A." by the Organization for European Economic Co-operation, and "Heavy Chemicals" by the Anglo-American Council on Productivity) were considered.

Sir Harold Hartley and Mr. J. Grange Moore initiated a wide discussion in which the most pre-eminent views were that industry needs more chemical engineers, but should also make better use of those it has. Prof. M. B. Donald warned the profession that it would find itself starved of entrants unless something were done to reduce the serious shortage of science teachers in grammar schools.

Around this central theme, covering the whole scope of chemical engineering, other papers were placed dealing with more specific developments in processes and techniques. Among these were contributions dealing with some unusual materials of construction. Thus, carbon and graphite (Mr. A. W. Morrison), tantalum and zirconium (Dr. G. L. Miller) and plastic materials (Mr. Verney Evans) were presented, and their special properties and applications in the chemical industries illustrated. Much interest was shown in these topics; and the importance of constructional materials, in that their development is often the limiting factor in the application of new processes, was stressed by more than one speaker.

The remaining papers presented to the conference dealt with chemical processes and chemical engineering techniques. Two interesting examples of specialist design and operation resulting from the penetration of chemical engineering fundamentals into two specific processes were provided by papers on milk processing plant (Mr. J. E. F. Renton) and formaldehyde production (Mr. K. Nickels).

The increasing use of chlorine throughout the industry made of timely interest a paper on developments in the production of chlorine in mercury cells (Mr. L. R. Thomas), particularly as the author drew many useful comparisons between alternative cell designs. A paper on advances in evaporation, with particular reference to the concentration of heat-sensitive liquids (Mr. B. N. Reavell), provided further examples of the application of a general technique to a specific problem. This provoked a lively discussion by its treatment of the economics of multiple-effect evaporation, as well as by a description of lesser-known systems, such as low-temperature climbing-film machines operating on the heat-pump principle.

Of more general interest was a review of developments in distillation since 1940 (Mr. G. A. Dummett). Although necessarily very compressed, the paper made an assessment of the important progress which has been made during the past thirteen years in fundamental physical data, in theoretical design methods and in practical industrial equipment.

In ranging from the very general comparison of the practice of chemical engineering in Great Britain and the United States to the wide distribution of a particular operation, this brief report discusses in a re-arranged order the papers of the conference and not in the order in which they were read.

T. K. Ross

BRITISH PHARMACEUTICAL CONFERENCE, 1953

The ninetieth British Pharmaceutical Conference was opened at Grosvenor House, London, on August 31, and more than six hundred pharmacists attended. The range of topics covered in the scientific sessions illustrates the extensive development of pharmaceutical research.

Fresh interests in the constituents of plants were demonstrated by several workers who have applied new methods of analysis. The quantitative estimation of the ergot alkaloids has been achieved by partition chromatography on cellulose columns, and colorimetric assay of the fractions shows that recoveries of pure individual alkaloids are consistent. The constituents of digitalis tinctures have been investigated, no correlation having been found between the potency of frogs to the glycosides and the intensity of the colour reaction. Other workers have applied paper-partition chromatography to the separation of the tropane alkaloids, their estimations being carried out by use of the Vitali–Morin reaction. The chromatographic method has been particularly useful in estimating the hyoscine and hyoscyamine content of *Datura sanguinea*.

From experimental work on the biogenesis of the tropane alkaloids some speculations have been made, and the results appear to indicate that the product of synthesis is related to the site of synthesis. The histochemical evidence for alkaloid production in meristematic tissues has been corroborated, and two other workers directed attention towards the root as the locus of alkaloid synthesis. Reciprocal grafts between tetraploid and diploid *Datura stramonium* have been made, and it was suggested that the genetical nature of the stock determines the alkaloidal content of scion and stock. In branch chimeras the tetraploid branch is richer in alkaloid than the diploid branch growing on the same root.

One curious fact has come to light as a result of a study of the anthraquinone glycosides of cascara, namely, that galenical preparations containing glycosides in amounts similar to those found in the crude drug are only half as active. The use of boiling water and autoclaving was stated to be a more efficient method of producing the dry extract of cascara than extraction with cold water; apparently, evaporation of the percolate under reduced pressure does not enhance the potency of the final product.

The use of dihydrostreptomycin and of penicillin as a mixed preparation raises an assay problem, and it has been established that the success of any microbiological method must depend on the absence of interference by dihydrostreptomycin. A further paper related to the origin of stimulation zones on penicillin assay plates, and attributed the cause, in part, to additional nutrients having diffused from the inhibition zones.

A method was described using small groups of guinea pigs for demonstrating the prolonged action of globin insulin and protamine zinc insulin. The guinea pig was recommended as a satisfactory test animal, whereas this demonstration cannot be carried out with the rabbit. Another paper compared the efficiency of two official pyrogen tests, and suggested that the further use of rabbits, which had once been used in a test in which pyrogen had been found, should be forbidden. The maximum degree of restraint which may be imposed on the rabbits should be specified and electrical thermometers should be used.

The work of several contributors was focused on the stability of some pharmaceutical preparations. Methods of assessing the chemical stability of procaine benzyl-penicillin in aqueous media were described. A study of different batches of vitamin B_{12} injections has shown that differences in potency are caused by exposure to daylight. Although copper is known to affect the stability of aneurine hydrochloride solution, it was pointed out that the same effect is greatly diminished in dry powders when stored at room temperature over long periods. The problem of assessing emulsion stability was considered, and the breakdown has been investigated over the temperature range 4–85° C. It is considered that globule-size frequency analysis yields a reliable picture of the internal state of the emulsion. Elevated temperature was proposed as an artificial breakdown stress for the evaluation of emulsion stability.

Pharmacological research on some synthetic drugs was reported, and one substance has proved of value as a substitute for *p*-amino-salicylic acid, appearing to delay the emergence of streptomycin resistance. A structural analogue of hydrocortisone has been prepared and found to inhibit the glyconeo-genetic activity of cortisone acetate in adrenalectomized rats.

Further research has been carried out on bacterial survival in systems of low moisture content, and oils suitable for use in 'sterility tests' have been ingeniously prepared. A limiting viable count technique has been modified. Also reported was the fact that, by using soluble surface-active agents in small amounts, cotton dressings will retain their absorbency better than the conventional type. Three papers read at the Conference made a useful contribution to the problem of evaluating antacids, and a further paper described a rapid method of determining calcium and magnesium by titration.

For many years pharmacists have been 'glass conscious' and aware of the necessity of controlling its quality and characteristics when used as containers for pharmaceutical preparations. With the latter comment one paper was introduced as a contribution to the symposium session, which dealt with the pharmaceutical aspects of glass and rubber. Experiences with containers and closures in the pharmaceutical industry were also discussed.

S. B. CHALLEN

MOVEMENT OF POSTGRADUATE SCIENCE STUDENTS

AMONG the activities of the British Council which are of direct interest to science none is more important than its encouragement of the movement of scientists, by bringing to Great Britain scientists, both postgraduates for purposes of advanced study or research, and more senior people to visit their opposite numbers, and by arranging for British scientists to pay lecturing or advisory visits overseas. This flow of scientists is, of course, only part of such movements, and because the funds available to the British Council for these purposes are limited, it is essential that they should be deployed in those directions where the need is greatest. This cannot be done effectively without a reasonably accurate knowledge of the flow of scientists promoted by other sources. Various publications indicate the awards available; but hitherto there have been no statistics showing the extent and characteristics of the flow which actually occurs.

For this reason the Executive Committee of the British Council in November 1951 agreed to the appointment of a working party of representatives of the Council itself, the Royal Society, the Department of Scientific and Industrial Research and the Medical and the Agricultural Research Councils, to review broadly and report on existing facilities for the movement of scientists, so as to arrive at a measure of the present scale of such activities, and to explore the need for any further co-ordination. The working party consisted of Sir Alfred Egerton, Dr. D. C. Martin, Dr. Alexander King, Mr. W. G. Alexander, Dr. F. H. K. Green (who withdrew later since in his opinion the examination was unlikely to yield data of use to medicine) and Sir Kenneth Loch, and it selected the calendar year 1951 as a sample period, deciding also to limit the investigation to the movement of graduate scientists whose journeys were made for the purpose of either advanced study or research. Assistance was sought from British universities, official bodies, trust funds and other organizations known to have an interest in this type of movement. For each individual information was collected on the professional status

of the scientist, his subject, the broad purpose and duration of his visit, and the country concerned.

Thanks to the willing and helpful co-operation of those approached, information was collected and analysed on the movements of more than five hundred scientists from Britain and some eleven hundred visiting Britain. It is believed that the survey covers more than 80 per cent of the total movements of this type, and that it is thus sufficiently comprehensive to give a useful cross-section of the whole flow. The statistics thus obtained are summarized in a series of tables, of which those relating to the movements to Britain and from Britain in 1951 by groups of countries and groups of subjects and to the comparative flow of scientists are reproduced as Tables 1 and 2, respectively, herewith. Of scientists visiting Britain from Commonwealth countries, 30 per cent stayed for more than three and less than thirteen months, and 55 per cent more than thirteen and less than twenty-five months; for scientists coming from foreign countries, the corresponding figures are 36 and 26 per cent, respectively, while 22 per cent stayed for less than one month. Of scientists going from Britain to Commonwealth countries, on the other hand, 35 per cent stayed for more than one but less than three months, and 39 per cent for more than three and less than thirteen months; for those going to foreign countries the corresponding figures are 22 and 42 per cent, respectively, while 30 per cent stayed for less than one month. The British Council offers to place selected information at the disposal of other bodies interested in the movement of scientists; inquiries should be addressed to Administrator, Science Group, British Council, 65 Davies Street, London, W.1. It is also recommended that British Council representatives should be provided with the survey data relating to their country and those contiguous to it.

It is apparent from the survey that the saturation point of useful effort in the movement of scientists has not been reached. Thus in Latin American countries, where science is of recognized importance, comparatively little was being done; but in others, such as Egypt, the effort seems to be adequate. At home the effort is limited by the number of vacancies which could be made available at universities and technical colleges for postgraduate research workers or students from overseas. It is unlikely that offers from authorities abroad would in themselves be sufficiently attractive to British postgraduates for them to wish to work in those countries, and hence, owing to the advantages which would also accrue to Britain, provision should be made for any financial assistance required.

The working party found some difficulty in suggesting any practical way of analysing attendances at conferences. Although it is of opinion that Britain should be better represented at scientific conferences abroad, particularly in more distant countries, the effect of the recent Treasury relaxation of currency restrictions for British scientists attending conferences in many countries could not be judged. In view of all the factors, the working party recommends that consideration of the question of greater facilities for the attendance of scientists at conferences should be deferred until the report of the Drogheda Committee is available.

SUPPLY AND EDUCATION OF MANAGERS FOR BRITISH INDUSTRY

A BOOKLET issued by the British Institute of Management contains the text of speeches delivered at the Second Scottish Conference held at Gleneagles during April 10–12. Among the subjects debated was that of finding the next generation of managers for British industry, and Dr. N. C. Hunt, referring to the figures supplied by Dr. E. Ashby, which indicate that industry will in future have to recruit its managerial staff from the universities because the reservoir of highly intelligent young people available outside the universities is drying up, discussed the kind of education and training which should be given to university students.

In his paper Dr. Hunt pointed out that, of hundreds of departments of business administration in the United States, only thirty are recognized by the Association of American Universities, and even if it does not matter what subjects are studied in developing the qualities desirable for administration, all subjects are not of equal value in giving the knowledge required. So long as normal university standards of teaching and research are maintained, Dr. Hunt thinks administrative studies could reasonably be included in a university curriculum. Postgraduate training might be given immediately after graduation or after some years of industrial experience; while the short courses offered at the Administrative Staff College, Henley-on-Thames, are extremely useful, they are not the whole answer, especially for the more junior executive who lacks the experience to profit from a course deriving its value from the interchange of experience rather than from formal study. There are already postgraduate courses in business administration at the Universities of London and Manchester and one is under consideration at Edinburgh, while there is a Department of Engineering Production at Birmingham. Dr. Hunt maintained that only in a university could be found the departments specializing in the basic disciplines out of which administration springs—economics, psychology, sociology, law and the applied sciences—and it is upon these that an advanced school of administration must be built.

In emphasizing that education for management must be a co-operative effort between the teaching institutions and industry, Dr. D. S. Anderson pointed out that in practice this means that industry must be willing to lend staff for lecturing in management courses; to accept trainees for long or short periods; and to take the trouble to arrange proper schemes of training as well as to supply frank particulars of successful and unsuccessful experiments and to second staff from time to time for further training. It also involves willingness on the part of academic staff to keep up to date by maintaining close contacts with industry, or even to return to industry for periods of 'refreshment', and that industry should be prepared to put some consulting work in the way of academic institutions because of the value which such work has in keeping a teaching staff in touch with actual practice. The content of courses does not present any serious problem; but it is essential that the various kinds of courses should not be limited to managers or potential managers, but should also provide for the training of workers' representatives. Dr. Anderson continued by saying that intelligent discussion—for example, in joint consultation—means intelligence on both sides of the table, and he thinks that only by education and training could one remove the feeling of inferiority to which lack of co-operation is so often due.

SUSCEPTIBILITY OF THE GUINEA PIG TO PHARMACOLOGICAL FACTORS FROM ITS OWN SERUM

By Drs. M. E. MACKAY*, A. A. MILES, C.B.E., M. SCHACHTER and D. L. WILHELM

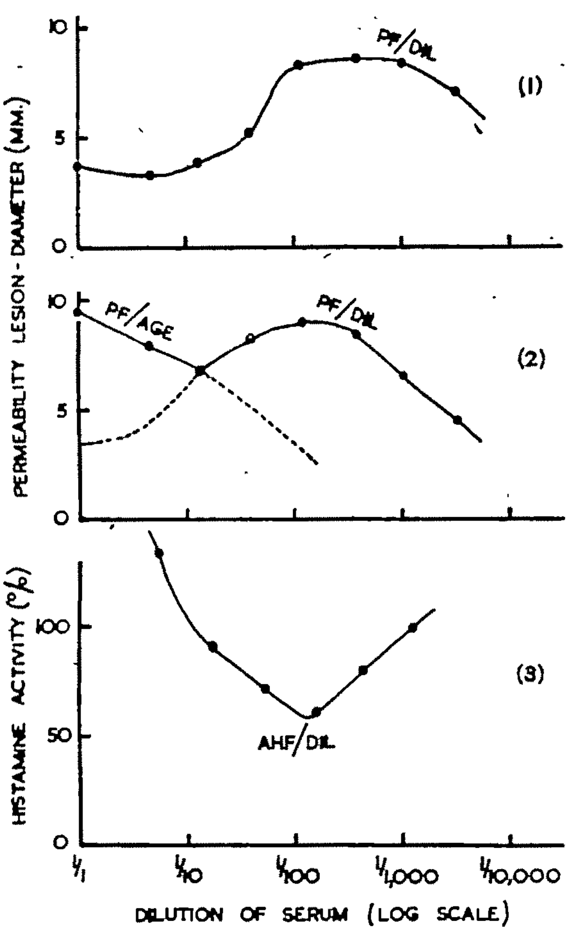
Lister Institute of Preventive Medicine, London, S.W.1

DURING a search in the guinea pig for endogenous substances responsible for the vascular and toxic phenomena of inflammation, we discovered in the blood serum of that animal a number of striking pharmacological activities, apparently due to substances of high molecular weight. Serum and serum-fractions proved to contain substances increasing the permeability of skin capillaries (permeability factors; PF), lowering the blood pressure (hypotensive factor; HF), and decreasing the smooth muscle contractor action of histamine (anti-histamine factors; AHF). None of these substances is demonstrable in fresh undiluted serum, but two are activated when the serum is diluted in 0·85 per cent saline: a permeability factor, PF/Dil; and an antihistamine factor, AHF/Dil. A second permeability factor accumulates in undiluted serum which has been held for several days at 2° C.; that is, on ageing of the serum. This we designate PF/Age.

PF/Dil. When 0·1-ml. volumes of serial dilutions of fresh serum are injected intracutaneously into depilated albino guinea pigs with pontamine blue in their circulation[1], within three minutes capillary permeability is substantially increased and the dye exudes into the injection site to form a circular blue lesion. Serum is activated only when it is diluted beyond 1/15–1/30. Maximum activation, as indicated by maximum average diameter of lesion, occurs at 1/100–1/400, and the activity is diluted out at about 1/5,000 (Fig. 1). The dilution effect is evident even in the animal from which the serum is obtained. The activation is to some extent reversible, because when diluted serum is reconcentrated at 2° C. by filtration of the saline through cellophan, it partly regains its inactivity. Unlike substances such as histamine or the histamine-liberator 48/80[1], the factor is not antagonized by mepyramine given in intra-peritoneal doses of 20 mgm./kgm. body-weight two hours before the test. It is relatively heat-labile, a 2 per cent solution of serum being largely inactivated by heating for 1 min. at 100° C.

---

* Working on behalf of the Medical Research Council.



PF/Age. This factor appears in undiluted serum after one day at 2° C. as a faintly blueing substance, and matures (Fig. 2) into a strongly blueing substance after three to five days. As the graph shows, its maximum is distinct from that of PF/Dil; and it is relatively inactive, the extrapolation of its curve indicating that it is diluted out at about 1/200. It is not antagonized by mepyramine.

AHF/Dil. Fig. 3 summarizes the striking effect of serum on the 15-sec. contractions of the guinea pig ileum induced by 0·05 μgm. histamine base, tested on the guinea pig ileum in an 18-ml. bath. The serum was diluted in a constant concentration of histamine, and the mixture held for a few minutes before adding to an 18-ml. organ bath. Neat or slightly diluted serum, even when it is by itself without action on the gut, enhances the histamine contraction. At about 1/40, AHF is activated; activation is maximum at about 1/100, and is diluted out at 1/1,500. Like PF/Dil, AHF/Dil is relatively heat-labile.

Activity of serum fractions. We located a permeability-factor and an anti-histamine factor in serum by the separation and assay of the protein components. A modification of the method of Kekwick and Mackay[2], using aqueous ethyl ether systems, was applied to pools of several guinea pig sera, and gave three fractions which were substantially albumin, α- + β-globulin, and γ-globulin. Either all or most of the pharmacological activity occurs in the second, the *G*2 fraction, which contains 20 per cent of the serum proteins, and is about half α- and half β-globulin. The activity is further concentrated by electrophoresis of this fraction, when it moves with the α-globulin. In this *G*2α fraction, we found not only a permeability and an antihistamine factor (PF/G2α and AHF/G2α) but also a hypotensive factor (HF/G2α). All three factors, besides migrating in an electrophoretic field as globulins, fail to pass a cellophan membrane, and are heat-stable, withstanding 100° C. for 1 min., but being largely destroyed after 10 min.; and all were unaffected when held for 24 hr. in buffers ranging from *p*H 4 to *p*H 9. We have as yet found no substrate or inhibitor indicating that the active materials are enzymic. The ether treatment during fractionation is not responsible for the activation of *G*2. Amounts of the *G*2α fractions are cited below as weight of protein (6·25 × nitrogen content).

PF/G2α has 1·6 times the permeability-inducing potency of histamine base. If it is assumed that *G*2α is all permeability factor and, being retained in cellophan sacs, has a molecular weight of greater than 20,000, on a molar basis the substance is more than 90 times as active as histamine. PF/G2α has a marked affinity for the skin tissue. Given intracutaneously, it is strongly leucotaxic, and strongly promotes the adherence of circulating leucocytes to the capillary walls. Given intravenously, in doses of about 1 mgm./kgm., it produces temporary collapse of the animal, and a moderate, general increase in permeability of the skin capillaries, as demonstrated by the method of Feldberg and Miles[3]. Both the intracutaneous and intravenous effects are resistant to mepyramine. *G*2α does not liberate histamine from perfused dog or cat skin[4], or from minced guinea pig skin incubated at 37° C.[5].

HF/G2α. In intravenous doses of 0·1–0·5 mgm./kgm., *G*2α produces a fall in carotid pressure and various degrees of over-breathing in anæsthetized guinea pigs; with the larger doses the hypotension is severe and lasts ten minutes or more. The dog is equally susceptible, the rabbit less so. In all three species, repeated injections at intervals of less than 3 min. induced some refractoriness. The hypotensive effect is not changed by vagotomy; it differs from that produced by histamine, acetyl-choline or 5-hydroxytryptamine; and is unlike the Brodie effect[6].

AHF/G2α. The *G*2α fraction, in concentrations of 0·2–0·5 mgm./ml., tested in the same way as AHF/Dil, partly antagonizes 0·05 μgm./ml. histamine when mixed with it before introduction into the bath. At room temperature the reaction between the two is complete in 30 sec., and is not altered during a subsequent 80 min. The antagonism is less when *G*2α is added to the bath first and histamine is added after. The inactivation is partly reversible, because within 10–20 sec. of adding the mixture, there is a second contraction of the gut, and this, like the first, is susceptible to mepyramine. But although the binding is apparently reversible, nevertheless it is not possible to extract free histamine from the hypothetical *G*2α-histamine complex by the usual extraction process with hydrochloric acid.

We have not yet established the relationships of these six factors. Of the three permeability factors, PF/Dil and PF/Age are almost certainly distinct. PF/Dil and PF/G2α, being the most active permeability factors in fresh and fractionated serum respectively, may be identical; though PF/G2α is more heat-stable than PF/Dil. In the same way the two anti-histamine factors may be identical; but, as with the two permeability factors, AHF/G2α is more heat-stable than AHF/Dil. With both pairs, however, the difference is not inconsistent with identity, because whole serum contains substances that confer on the heat-stable $G2\alpha$ fraction the heat lability of the permeability factors and anti-histamine factors produced by dilution. As regards the permeability, histamine and anti-histamine effects of the $G2$ fraction, the physicochemical similarity of the $G2\alpha$ factors suggests their identity. We have some additional evidence that PF/G2α and HF/G2α are the same, but none as yet for other identities. As regards the two 'dilution' factors, PF/Dil and AHF/Dil, certain quantitative discrepancies suggest that if PF/Dil is identical with PF/G2α, then AHF/Dil is not the same as the AHF/G2α.

Toxic effects by mammalian sera in the tissues of *heterologous* species are not uncommon; but any estimate of their significance must be dominated by considerations of species incompatibility. The interest of the serotoxic factors we describe is threefold: (1) they are large molecular substances, effective in the *homologous* species, even in the individual animal from which the serum is obtained; (2) they are readily activated by dilution or by relatively gentle processes of serum fractionation; (3) some limited explorations suggest that the phenomena occur with the sera of mammalian species other than the guinea pig.

We may therefore be dealing with substances from the animals' own tissues which are readily activable *in vivo*, and which have a natural role in the reactions of mammalian tissues to injury. [Aug. 15.

ASPECTS OF VITAMIN A DEFICIENCY IN RATS

By J. S. LOWE, PROF. R. A. MORTON, F.R.S.
Department of Biochemistry
and PROF. R. G. HARRISON
Department of Anatomy, University of Liverpool

THE accepted signs of vitamin A deficiency are (1) defective low-intensity vision, (2) retarded growth leading to loss of weight, (3) hyperkeratosis (keratinizing metaplasia), and (4) xerophthalmia.

The usual biological assay is carried out on rats depleted to the point of rapid loss of weight. Such rats may or may not exhibit xerophthalmia and in most assays do not. The response is a quick resumption of growth and the cure of any xerophthalmia.

The defective low-intensity vision is measured by delayed dark adaptation, reflecting slow regeneration of rhodopsin. Retinene$_1$ (vitamin A aldehyde) and vitamin A alcohol, linked through the operation of alcohol dehydrogenase, play a direct part in scotopic vision as they form an integral part of the light-sensitive rhodopsin[1]. Whatever refinements future research may bring, the mode of action of vitamin A in scotopic vision is in broad outline a solved problem.

These results are in striking contrast to the state of knowledge concerning the growth-promoting and anti-xerophthalmic action of vitamin A. Practically nothing is known concerning the 'systemic' mode of action, and the position has been reached with vitamin A (as with vitamin D) that the problems of structure and synthesis have been solved while the essential biochemical problems are halted.

We wish to make a preliminary report of experiments which seem to break new ground.

(*a*) *The depletion process.* Newly weaned rats on a diet including light white casein (B.D.H., Ltd.) continue to grow slowly long after no vitamin A can be found in liver, kidney or blood. When fully dark-adapted, the retinas of such rats yield normal rhodopsin extracts. The light white casein contains traces of vitamin A and β-carotene, which can only be removed by refluxing the casein for several hours with ethanol. The vitamin A-activity is about 0·5 I.U./gm., assuming optimal conversion of provitamin A (β-carotene) to vitamin A. This activity is made up of 0·3 I.U. vitamin A and 0·08 μgm. β-carotene in each gram of light white casein. This may not, however, be a full measure of the potential activity of light white casein, as refluxing with ethanol is rather drastic; but it is clear that 1–2 I.U./day will maintain slow growth in rats with no signs of illness or of xerophthalmia. If, however, the light white casein component of the diet is first exhaustively extracted with boiling ethanol, growth eventually ceases and xerophthalmia appears regularly. The vitamin A in the retina and pigment epithelium does not, however, appear to be readily mobilized for use elsewhere, because the rhodopsin extractable from the retinas of xerophthalmic animals is qualitatively and quantitatively normal.

(*b*) *The specificity of vitamin A.* Several groups of workers[2-6] have claimed that growth can be restored and xerophthalmia cured in vitamin A-deficient rats given dietary supplements free from preformed vitamin A or known carotenoid precursors. Kaunitz and Slanetz[7,8] claimed that lard contained a vitamin A-replacing factor which could be concentrated in the first 7 per cent eliminated by simple molecular distillation. When given at the level 2 per cent (w/w) in a vitamin A-deficient diet, the distillate proved more effective than 7·5 I.U./day of vitamin A palmitate as a supplement to the control diet.

We have found that a lard distillate (kindly prepared for us by Dr. R. E. Stuckey and Mr. A. W. Davidson, of British Drug Houses, Ltd., London) was only partially effective at the 2 per cent dietary level, but at 5 per cent was completely effective in restoring growth and curing frank xerophthalmia; 0·6 gm./rat/day elicited a response similar to that of 6 I.U./rat/day of preformed vitamin A. The lard distillate contained no vitamin A or provitamin A (β-carotene) detectable by any colorimetric or spectrophotometric test before or after chromatography.

The importance of the lard factor is that since it is obviously distinct from vitamin A, the protective action of one or the other (or both) must be indirect unless the idea that both control the same fundamental biochemical processes is abandoned.

The deficiency syndrome (apart from its retinal aspect) may be a secondary effect correctable in alternative ways. This idea is not out of line with repeated failures to detect vitamin A in epithelial tissues[9], and it becomes necessary to inquire whether xerophthalmia is due less obviously to the absence of vitamin A than to the presence of some abnormal

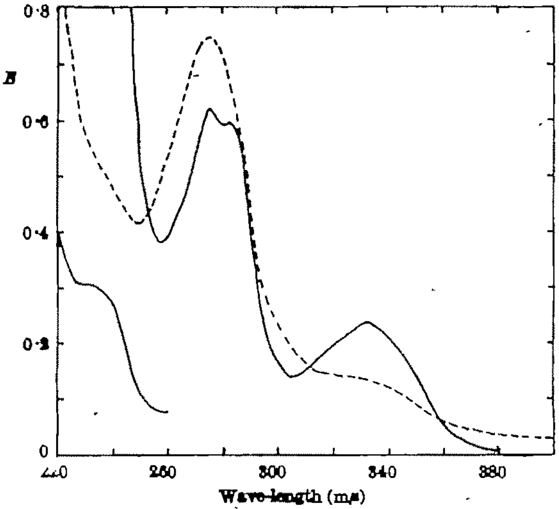

Fig. 1. (a) Continuous line, absorption spectrum of the richest fraction of 233 mμ, 275 mμ, 283 mμ, 332 mμ material. 220–250 mμ = 0·002 per cent solution; 250–380 mμ = 0·01 per cent solution. $E^{1\%}_{1\,\text{cm.}}$ 233 mμ, 151; $E^{1\%}_{1\,\text{cm.}}$ 275 mμ, 62; $E^{1\%}_{1\,\text{cm.}}$ 283 mμ, 59·5; $E^{1\%}_{1\,\text{cm.}}$ 332 mμ, 23·7

(b) Broken line, absorption spectrum of a typical additional fraction from a chromatographic separation of vitamin A-depleted rat liver lipid unsaponifiable matter. 0·0094 per cent solution. $E^{1\%}_{1\,\text{cm.}}$ 275 mμ, 80; $E^{1\%}_{1\,\text{cm.}}$ 330 mμ, 14·7. Solvent in both cases is *cyclo*hexane

metabolite(s) usually kept in check by the presence of vitamin A.

(c) *Liver lipid unsaponifiable matter from vitamin A-deficient rats.* The absorption spectrum of the unsaponifiable fraction of liver lipids shows λ

(c) *Liver lipid unsaponifiable matter from vitamin A-deficient rats.* The absorption spectrum of the unsaponifiable fraction of liver lipids shows $\lambda_{\text{max.}}$ 275 mμ with an inflexion near 330 mμ at the stage of depletion when no blue colour with antimony trichloride can be obtained with fractions from blood, kidney or liver. Chromatographic methods permit the concentration of a material showing (in *cyclo*hexane) $\lambda_{\text{max.}}$ 275 mμ and 332 mμ with marked inflexions at 233 mμ and 283 mμ. Some fractions obtained at the same time show $\lambda_{\text{max.}}$ 275 mμ with much weaker absorption near 330 mμ and no inflexion at 283 mμ. These materials have never been recorded as present in normal rat-liver lipid unsaponifiable fractions.

Using rats more fully depleted of vitamin A by the use of an alcohol-extracted casein diet, the amounts of abnormal constituents are found to have increased considerably. The most important fraction is eluted from alumina (P. Spence and Co., Grade 0, weakened by addition of 2 per cent water) by 8 per cent diethyl ether in light petroleum. The spectrum of the richest fraction is shown in Fig. 1, together with that of another fraction regularly obtained in the course of chromatographic separations.

The evidence indicates that a series of new substances appears in the liver in the later stages of vitamin A depletion.

In order to exclude the possibility that the new selectively absorbing materials arose from some peculiarity in our strain of rats or our experimental diets, the co-operation of Dr. S. Y. Thompson, of the National Institute for Research in Dairying, was enlisted. The livers from three groups of six rats prepared in the normal way at the Institute for vitamin A bio-assays were sent to Liverpool and examined promptly. All three sets gave extracts completely confirming our findings for rats having no liver or kidney reserves but not showing xerophthalmia.

(d) *Xerophthalmic eye tissue.* Tissue around the eyes of rats exhibiting marked xerophthalmia was excised and the lipid unsaponifiable fraction examined spectroscopically. The absorption curve showed three maxima (260, 270, 280 mμ) and an inflexion (320 mμ) superimposed on rising general absorption. The curve obtained with similar material from control rats (that is, weanlings on a synthetic diet supplemented with 10 I.U. vitamin A/day) showed only general absorption.

(e) *Abnormal constituents of other liver lipids.* Liver lipid unsaponifiable fractions from aged, worn-out horses (knackers' yard) showed $\lambda_{\text{max.}}$ 270 mμ. These horses had very low vitamin A reserves and the livers were probably richer in abnormal constituents than the livers of horses killed for meat in the abattoir. Among the substances present was Δ 3 : 5-cholestadiene-7-one, but at least one other substance with $\lambda_{\text{max.}}$ 270 mμ (in *cyclo*hexane) was present[10].

(f) *Cholesterol–vitamin A interactions.* In the vitamin A-deficient rat there is evidence of a significant increase in blood cholesterol[11,12], and on the other hand it has been shown that a high cholesterol intake depresses the liver store of vitamin A (rats, cockerels)[13].

(g) *Vitamin A depletion and the adrenal cortex.* The adrenals of thirty-one vitamin A-deficient rats, fourteen of which had severe xerophthalmia, were examined histologically and histochemically by one of us (R. G. H.). Frozen sections of both adrenals, after fixation in formal calcium, were subjected to the sudan black technique[14] for total lipids in five rats, and to the acid hæmatein method[14,15] for phospholipin in four rats, while in fifteen rats one adrenal was subjected to the sudan black technique and the other to the acid hæmatein method, and in seven rats the sudan black technique was used on one adrenal, and Schultz's method of application of the Liebermann–Burchard method for cholesterol and its esters on the other. All the rats were from a colony inbred for many generations and were litter-mates in many cases.

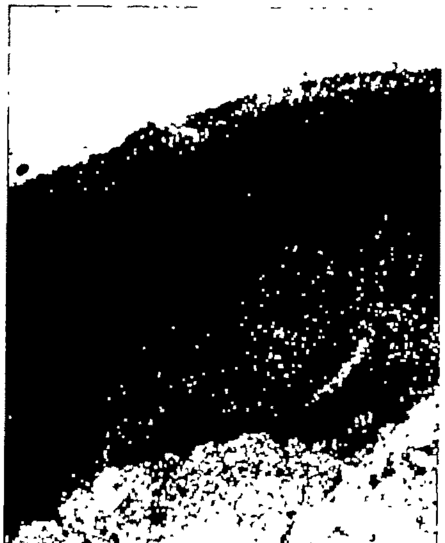

Fig. 2. Photomicrograph of the distribution of lipid in a part of the adrenal cortex of a vitamin A-deficient rat as shown by the sudan black technique. The zona glomerulosa (uppermost in the figure) is heavily loaded with lipid, especially top left, where there is obliteration of the sudanophobe zone, and also the outer zona fasciculata (× 71)

In contradistinction to Stoerk, Kaunitz and Slanetz[17], no 'hyaline droplet' change of the adrenal cortical cells was noted, and in agreement with earlier authors[14–16] no pathological change in the histological structure of these cells could be detected. The histochemical appearances of the adrenal cortex were, however, of great interest. The distribution of lipid, as shown by the sudan black technique, is within normal limits (Fig. 2), except that the amount of lipid in parts of the zona glomerulosa is very much increased above normal in seventeen of the rats examined (both sexes), and that the lipid distribution is uneven in parts of the zona fasciculata; the well-loaded parts of the zona fasciculata showed lipid droplets similar in distribution, size and characteristics to those previously described as 'hyaline' droplets[17]. The only exception to this appearance occurred in two rats in which lipid was completely absent from all parts of the adrenal cortex except the zona glomerulosa. The phospholipin content of the adrenal cortex, however, as shown by the acid hæmatein test, differed considerably in its distribution and loading from the lipid; in all the rats examined, apart from three, in which the distribution of phospholipin is within normal limits, the only phospholipin to be found is restricted to the zona glomerulosa, the zona fasciculata and zona reticularis being completely devoid of any coloration (Fig. 3), except in six rats in which there is an outer rim of coloured zona fasciculata cells, immediately subjacent to, and about the same thickness as, the zona glomerulosa. The distribution of cholesterol, in the adrenals examined, corresponds to that seen in the normal adrenal cortex, except in two adrenals (Figs. 4 and 5) in which the cholesterol is confined to the zona glomerulosa.

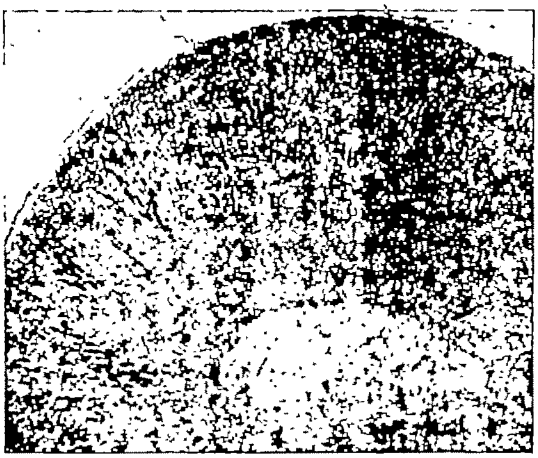

Fig. 3. The distribution of phospholipin in the adrenal cortex of a vitamin A-deficient rat as shown by the acid hæmatein method. As compared with Fig. 2, note that the phospholipin is restricted to a small quantity in the zona glomerulosa. The functioning blood vessels are also demonstrated, since the blood corpuscles are coloured by this method (× 47)

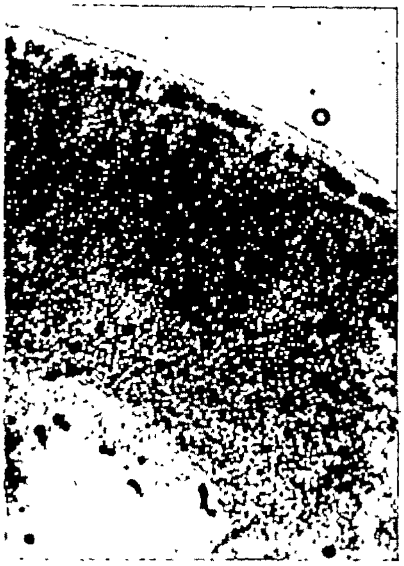

Fig. 4. The distribution of cholesterol in the adrenal cortex of a vitamin A-deficient rat as shown by the Liebermann–Burchard method. The cholesterol is confined to the zona glomerulosa and zona fasciculata, in correspondence with the sites of heavy loading with lipid (× 71)

There is, therefore, a dissociated reaction of the adrenal cortex in the vitamin A-depleted rat to the sudan black technique and Schultz reaction on one hand, and the acid hæmatein method on the other. Whereas the distribution of lipid and cholesterol is within normal limits, phospholipin content is reduced and confined to the zona glomerulosa. This is a state of affairs never seen in the normal adrenal cortex[11,22] and suggests some disorder in the metabolism of adrenal cortical cells in vitamin A deficiency with consequent alteration of their secretory activity. This contention is supported (*a*) by the histochemical reaction of the zona glomerulosa to both sudan black and acid hæmatein, (*b*) by the increased vascularity of the adrenal cortex (Fig. 3), and (*c*) if the presence or absence of the sudanophobe zone be taken as an indication of the level of cortical activity, by the presence of a sudanophobe zone in some of the female rats and its absence in some of the male rats, together with the absence of a sudanophobe zone in parts of an adrenal cortex where it normally is mainly found (Fig. 2). If the theory of morphological and functional independence of the adrenal cortical zones[11–22] be accepted, it would appear that there is some abnormality in the glucocorticoid activity of adrenal cortical secretion, while the secretion of mineralo-corticoids is unaffected or even enhanced.

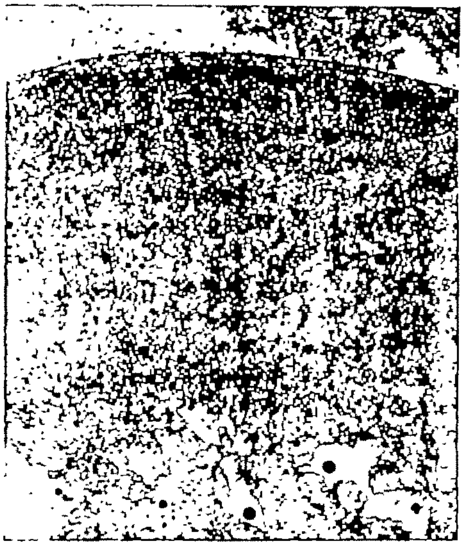

Fig. 5. The distribution of cholesterol in the adrenal cortex of another vitamin A-deficient rat in which the cholesterol is confined to the zona glomerulosa (× 71)

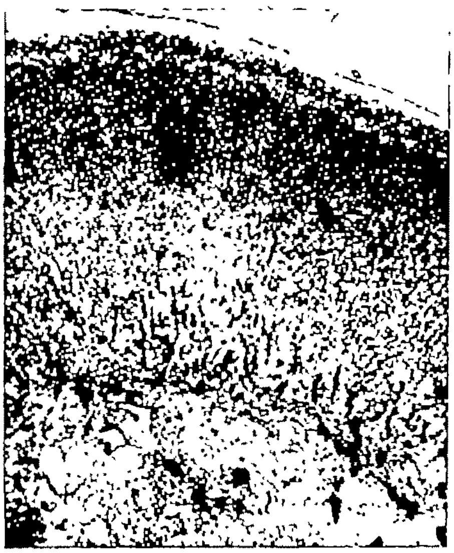

Fig. 6. The appearance of the adrenal cortex of a rat maintained on the light white casein diet (containing 1 per cent sodium chloride) for 120 days, and then given 6 I.U. vitamin A for 70 days, as shown by the acid hæmatein technique. Phospholipin is present in the zona glomerulosa and outer zona fasciculata. Blood vessels in zona reticularis can also be seen (× 71)

The adrenals of a number of rats which had shown a growth response to lard or vitamin A after being fed for a lengthy period on the light white casein diet with its very low vitamin A content were also examined. In one animal which had been given the diet (containing 1 per cent sodium chloride) for 120 days and then 6 I.U./day vitamin A for seventy days, the histochemistry of the distribution of the lipid, phospholipin and cholesterol in the adrenal cortex was normal in all respects (Fig. 6). So also were the adrenals of a rat which had been fed the same diet for 128 days since weaning but had then shown an excellent growth response to a diet containing lard (20 per cent) administered for seventy days.

A curious effect occurs with young rats on the normal light white casein diet (without 1 per cent sodium chloride).

Two rats on this diet for thirty-five days after weaning received 10 I.U./day vitamin A throughout, while two others received 10 I.U./day for thirty-two days and 500 I.U./day for the last three days. In spite of this supplementation, which is more than adequate for growth and the prevention of xerophthalmia but marginal for liver storage, all four animals had adrenals histochemically identical with those of the much older animals exhibiting the full deficiency syndrome (frank xerophthalmia).

It therefore appears that the age of the rat, the duration and level of vitamin A administration and the sodium chloride intake require further study before the histochemistry of the adrenal cortex can be fully elucidated for vitamin A-deprived rats, although the dissociated histochemical reaction in avitaminosis A is clear cut.

Discussion

It is clear that as the rats approach the terminal stages of vitamin A-deficiency, hitherto unknown metabolites accumulate in the liver. There are notable changes in the histochemical appearance of the adrenal cortex and degeneration of epithelial tissues with xerophthalmia. The rats had been so thoroughly depleted that it is impossible to attribute the new metabolites to vitamin A as a precursor, and both from the spectroscopic properties and the amounts formed, the best working hypothesis is that they result from a lifting of restraint on the dehydrogenation of cholesterol or steroid hormones.

The absorption spectrum of the main new product has not been traced to a known steroid; but it shows a marked resemblance to that of certain β-naphthalenic compounds.

Work is in progress aiming at separating, characterizing and identifying the new lipid constituents and establishing their physiological properties. The important point, however, is that the concept of vitamin A-deficiency has been widened in a manner amenable to experimental attack. The discovery that certain metabolites accumulate in other deficiency states was the prelude to rapid advances in the elucidation of modes of action of some water-soluble vitamins. Perhaps the time is ripe for similar advances in the field of fat-soluble vitamins.

It is necessary to refer briefly to *X*-disease[24] (hyperkeratosis) of cattle. This new condition has caused serious losses throughout the United States and has been the subject of much recent study. It is usually due to the presence of toxic material in the food and can be produced by administering tri-, penta-, hexa- or octochloronaphthalene (used in lubricants and tractor crank-case oil)[25], but an active fraction in processed wheat concentrates appears to be different[26]. The disease is in some ways very similar to avitaminosis A. The causative agents added to the diet result in persistently low plasma vitamin A-levels, perhaps following diminished formation of vitamin A from β-carotene[27].

The fact that hyperkeratosis in vitamin A-deficiency results in the accumulation of our new substances in the liver may well be relevant to the observations on *X*-disease, and their interpretation.

The investigations on the histochemistry of the adrenal cortex were aided by a grant to one of us (R. G. H.) from the Medical Research Council, and by the technical assistance of Miss B. Birkett. [May 22.

Possibility of Movements of the African Migratory Locust in the Solitary Phase and the Dynamics of its Outbreaks

THE discovery of 'outbreak areas' of several species of locusts, and the influence of these discoveries on the setting up and organization of preventive control, have been described by Uvarov[1]. For the African migratory locust, *Locusta migratoria migratorioides* (R. and F.), the outbreak area, first indicated by Lean[2], was defined in detail at the Fifth International Anti-Locust Conference[3] in 1938. It has since been assumed that outbreaks of this species originate in this circumscribed area in which both population-increases and phase-transformation occur. On the basis of this information, a permanent International Preventive Control Organization was formed[4].

During recent years, evidence has been accumulating which indicates that, although this is undoubtedly the area where phase transformation takes place, the population of locusts is not confined to it throughout the year, and that seasonal migrations of solitary locusts occur, followed by breeding and sometimes by great increase in numbers, in regions as far as 100 km. from the centre of the outbreak area. Since 1951 the possibility of such migrations has been studied.

The topography and vegetation of those parts of the flood plains of the middle Niger usually referred to as the outbreak area have been described in detail by Lean[2] and Zolotarevsky[5]. To the west of the flood plains, there is a semi-arid zone where sandy soils predominate and where the vegetation is of a type capable of withstanding a severe dry season lasting from October until May. The region is known locally as the Farimaké, and it is here that the temporary appearance of locust populations has been studied during the dry seasons of 1951–52 and 1952–53. The events described below followed exactly the same sequence in both years; but in 1952 the densities of adults were much higher and changes were therefore more easily observed.

In 1951, adult locusts were present in the Farimaké in November and December. No nymphs were found; but the presence of exuviæ at the bases of the grasses suggested that the young adults found had been bred in that area. At the beginning of 1952, this population of young adults disappeared and, apart from scattered individuals, the region remained unpopulated until many months later. Some weeks after the disappearance of these locusts from Farimaké, adults appeared on the flood plains in areas which had, for some months, been reported clear.

In November 1952 we returned to the Farimaké. *Locusta* adults and nymphs were again present, in great numbers. At the same time, the flood plains, with the exception of a few higher areas never covered by the water, were deserted. Densities of adults in the Farimaké reached as high as 30 per 100 paces, and from the presence of numerous nymphs it was concluded that this generation was produced there. There is therefore no doubt that successful breeding can and does take place in these semi-arid regions during the rainy season.

The origin of the adults which gave rise to these nymphs and young adults was obscure; but since a repopulation of the Farimaké occurred after our previous visit, and corresponded with a fall in densities throughout the flood plains, it was tempting to assume a movement of solitary adults from the latter to the former.

From November 1952 onwards, the changing densities of adult locusts in the Farimaké were followed in detail. There was, soon after the beginning of November, a marked fall in numbers in most areas. This continued throughout the next month until, by the middle of January 1953, the population had disappeared. It is certain that this decline in numbers was not caused by the death of these young adults. No corpses were found and not one parasite was present in the many hundreds of locusts dissected. The effect of predators appeared to be negligible except perhaps for the numbers destroyed by predatory birds patrolling the edges of the numerous bush fires; but even this loss was much less than expected. In certain habitats the disappearance of the locusts occurred very suddenly; for example, at Dioura, the population fell from a density of 15–20 per 100 paces to less than one per 100 paces between December 31 and January 2.

About one week after the last rapid decline in numbers in the Farimaké in early January, adult locusts appeared in other areas from which they were absent until then. Such adults seemed in every way similar to those previously present in the Farimaké. One of the newly populated areas was on the edge of the flood plains about 15 km. from parts of the Farimaké where densities had been high. All the others were within the flood plains and about 20 km. from the borders of the Farimaké. Locusts on the edges of the flood plains were found under normal conditions; but those within the flood plains were taken from grasses standing in water. Densities in such habitats reached as high as 15 per 100 paces. By the end of January similar adults were present on the edges of the 'toguerés' (small hills within the flood plains which are never completely covered by the floods) among the grasses recently uncovered by the floods. No hoppers were seen until nearly two months later, and there could be no doubt that these populations represented an influx from elsewhere. These habitats in the flood plains were occupied one month earlier in 1953 than in 1952; but the dates in both years corresponded with the uncovering of them by the retreat of flood water. This indicates that the adults were not far from these habitats when they became suitable, and it also suggests that movements over longer distances may be made in easy stages.

The locust population of the grass habitats above the water declined in February and, at the same time, the numbers increased on the edges of the toguerés and on a few higher parts of the plain already uncovered by the retreat of the floods. Densities in these places reached the maximum seen on the flood plains and again corresponded with those previously observed in the Farimaké.

The evidence given above is only circumstantial; all efforts to obtain direct proof were unsuccessful. In this connexion a method of marking locusts in rather large numbers and without the necessity of capturing them has now been developed. The apparatus is simple, consisting of a small spray-gun with a reservoir holding one litre of liquid, pressurized by a built-in hand pump and with a trigger mechanism, which projects a fine jet of a suspension of pigment in light oil on to the locust without catching it. With practice, individual locusts can be marked even in flight. By this method about seventy locusts could be marked in an hour with one gun, whereas six collectors could mark only thirty by hand in the same time. Marked locusts have been captured fifteen days after marking and up to 7 km. from the place where they were marked. It has not yet been possible to test this method on a large scale, but the results so far obtained warrant further attempts to obtain a direct proof of these suspected migrations by its use.

An interesting aspect of the problem is the time of day at which these movements may occur. Despite constant observations, no spontaneous flights have ever been seen in daylight hours. Some observations at night have shown that locusts may make normal flights on being disturbed even when the temperature is several degrees lower than that recorded at dusk, and on several occasions adult locusts have been taken at light, suggesting that nocturnal flights occur.

Assuming that these large-scale movements are not exceptional, it is necessary to consider their importance in connexion with outbreak control. The Farimaké appears to be an area where breeding during summer rains may result in a great increase in population. The numbers of locusts produced there presumably determine the numbers which will later move to the outbreak area, where they would contribute to the production of incipient bands. Surveys in the Farimaké at the end of rains would possibly help the control organization to estimate the likelihood of band production in the following spring and to make preparations accordingly. Of course, the arrival of large numbers of adults will not necessarily give rise to bands in the outbreak area, as this depends on the factors operating within the outbreak area controlling successful breeding and phase transformation, and these factors have not yet been studied. In any event, however, the supervision of locust populations must not be restricted to the outbreak area proper, and a wider organization may be necessary for control purposes.

I wish to thank the Nigerian Government for allowing me to carry out these studies and the Provisional International Committee for the Control of the Migratory Locust for making them possible. My thanks are also due to Mr. M. Roblot, director of the Aire Grégarigène, for generously placing at my disposal all the information and material of his organization, and for facilitating my work, and to Drs. B. P. Uvarov and B. N. Zolotarevsky for their help and advice.

Rate of Flow of Polycrystalline Ice

Attempts to describe the flow of glaciers theoretically have been hindered by lack of knowledge of the actual behaviour of ice under stress, and for this reason experiments have been made on blocks of polycrystalline ice with random orientation. The method of preparation of such blocks and preliminary results of compression tests on them at – 1·5° C. have already been briefly reported[1]. Further compression tests have now been made at – 12·8°, – 6·7°, – 1·5° and – 0·02° C.

At all the testing temperatures, creep curves were obtained similar to the one shown in the previous paper[1] (an ordinary creep curve with a transient and a quasi-viscous stage), although at the higher stresses a tertiary or accelerating stage was also found, which was attributed to the effect of recrystallization.

In order to compare tests at various stresses and temperatures, the logarithm of the minimum rate of strain observed in each test has been plotted against the logarithm of the compressive stress applied to produce it in Fig. 1, different symbols being used for points at different temperatures. It will be seen that the points for any given temperature lie reasonably close to a straight line. These lines correspond to relations between compressive stress σ and rate of strain $\dot{\epsilon}$ of the form:

$$\dot{\epsilon} = k\sigma^{n}, \qquad (1)$$

where k is constant for a given temperature and n takes the value 3·3. Some tests were also made in which the stress was raised or lowered during straining. In all these cases the rate of creep soon settled down to a steady rate not very different from that which it would have had if the final stress had been applied from the start. Points corresponding to such steady rates obtained after changing the stress at – 1·5° have been added to Fig. 1, and are shown by distinctive symbols.

The variation of minimum rate of creep with temperature is such that, for the three lower temperatures, the rate of strain at any given stress is related to the temperature by

$$\dot{\epsilon} = A \exp(-Q/RT), \qquad (2)$$

where A is constant for a given stress, R is the gas

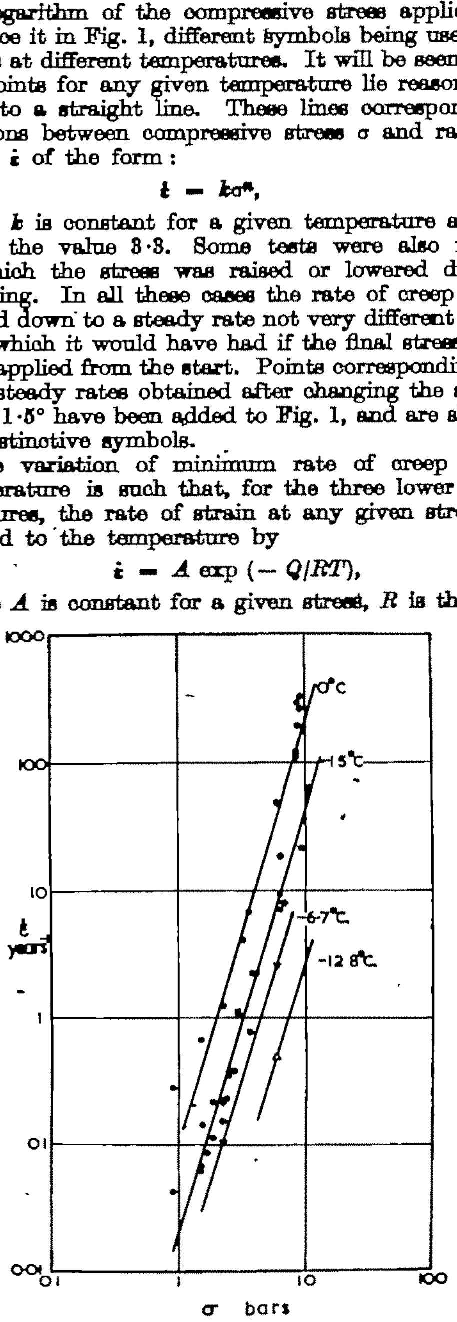

Fig. 1. Plot of logarithm of minimum rate of creep of ice against logarithm of stress. ●, points from creep tests very close to the melting point; ○, points from tests at – 1·5° C.; ◇, points from tests at – 1·5° C. after increasing the stress; □, points from tests at – 1·5° C. after decreasing the stress; ▼, points from tests at – 6·7° C.; △, point from test at – 12·8° C.

constant, T the absolute temperature and Q an activation energy of 33·4 k.cal. per mole. The rate of strain at the highest temperature is some four times higher than would be predicted from the formula, and this is attributed to local melting caused by temperature fluctuations.

The above results are helpful for understanding the mechanism of glacier flow, but it must be emphasized that the relations found here are not necessarily exactly those occurring in glaciers. The rate of strain plotted here is the minimum observed during the test. In tests at the higher stresses, tertiary creep produced a further acceleration after this minimum rate, which, under continued application of such stress, would make ice creep at a rate faster than the minimum; and it is far from certain that a similar acceleration would not have occurred in other tests, had they been continued for times of the order of years. The curves at the lowest stresses also gave points which may be in error, for because of experimental difficulties these tests, particularly at − 0·02° C., could not be continued long enough for the transient creep to be negligibly small. The creep curves at − 0·02° C. have therefore been re-examined, and assuming the transient creep obeys Andrade's $t^{1/3}$ law (as it appears to do within experimental error), the true quasi-viscous creep-rate has been calculated. The effect of this is to move the points at the lower stresses to lower rates of strain, and the best straight line through these points corresponds to a value of the exponent n in equation (1) of approximately 4.

Further details of these tests, as well as data obtained from sections about the grain size and recrystallization of these specimens, will be published elsewhere.

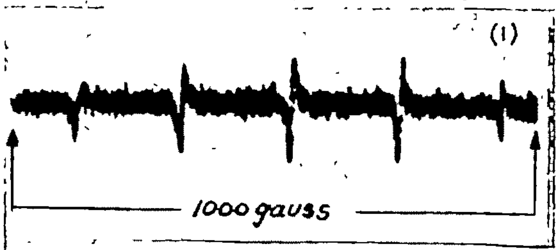
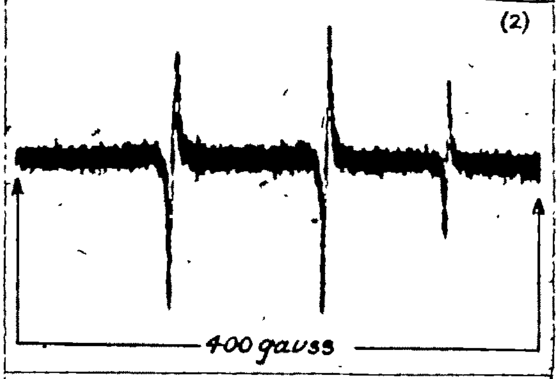
A Rapid Method of obtaining Nuclear Magnetic Resonance Spectrograms

Torrey[1] has discussed the possibilities of using a relatively rapid approach to resonant conditions as a method of searching for unknown nuclear resonances, and has described methods in which H_1 (the radio-frequency field) has been pulsed. Where the establishment of resonance conditions is rapid compared with the spin-lattice relaxation time, this method gives theoretically a larger nuclear signal than that available in cases where the resonance is excited continuously or frequently. We have found that a method whereby H_1 is fixed and H_0 (the D.C. magnetic field) is rapidly swept over a relatively wide range provides not only a simple method of demonstrating nuclear resonance effects, but also one that has possibilities in rapid searching for unknown resonances.

Fig. 1 is an oscillogram which shows the quadrupole splitting of the aluminium-27 (spin 5/2) resonance in a sample of synthetic sapphire weighing 1·5 gm. The signal/noise values in this oscillogram, which took one second to trace out, compare favourably with those obtained by other methods using times as long as twelve hours to cover the same region. Figs. 2 and 3 are two other typical oscillograms obtained by this method.





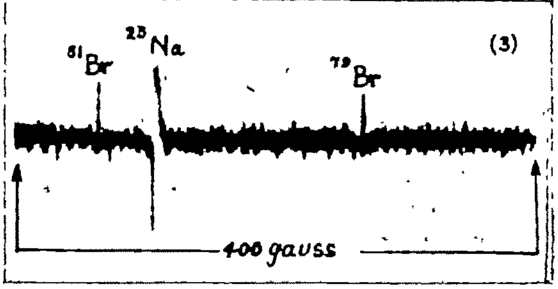


Fig. 1. Quadrupole splitting of aluminium-27 (spin 5/2) in a single crystal of aluminium oxide

Fig. 2. Quadrupole splitting of sodium-23 (spin 3/2) in a single crystal of sodium nitrate

Fig. 3. Spectrogram of a solution of sodium bromide

We have used a crossed-coil nuclear induction system similar to that described by Bloch[2]. The radio-frequency field H_1 was maintained at a frequency of 3 Mc./s. by a crystal-controlled oscillator and had the value of 0·5 gauss. The phase of the signal appearing at the output terminals of the bridge was adjusted so as to allow the dispersion component of the resonance to be observed. This signal is fed, after radio-frequency amplification, detection and low-frequency amplification, to the Y-plates of a cathode-ray oscilloscope.

A large and relatively sudden change in the D.C. field was made by short-circuiting a resistor in the driving circuit of the electromagnet. The value of the resistor was selected so that the rate of change of field was effectively linear over the region being investigated. Rates of change of 100–1,000 gauss per sec. were used. Simultaneously with the commencement of field-change, a suitable voltage was applied to the X-plate to give a single sweep of duration 1 sec. and of constant velocity. A photograph of the traverse of the spot across the cathode ray oscillograph produced a field spectrogram with the transient responses of the nuclei appearing as vertical displacements.

The samples used for obtaining the spectrograms shown in Figs. 2 and 3 were, respectively, a single crystal of sodium nitrate weighing 2 gm. and a solution containing 0·5 gm. of sodium bromide in 1 c.c. of distilled water.

Acknowledgment is made to the Chief Scientist, Ministry of Supply, for permission to publish this communication.

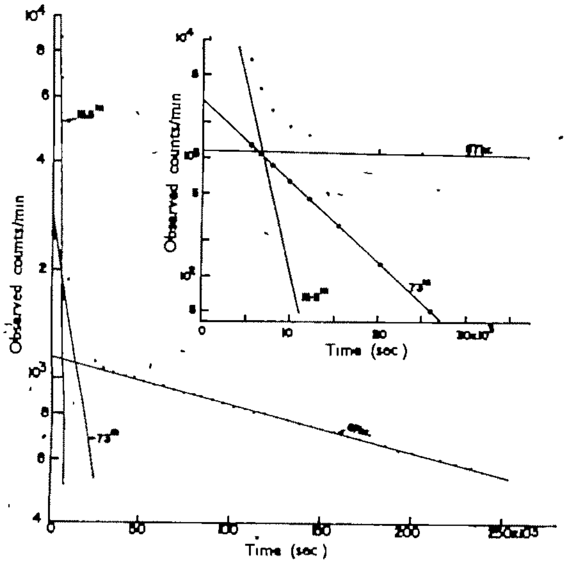
Isomeric States of Molybdenum-93

CONSIDERABLE interest has recently been focused on the 6·7-hr. isomeric state of molybdenum-93. Experiments by Alburger and Thulin[1] at Stockholm, as well as the earlier work of Boyd and Charpie[2], definitely assigned this isomeric state to molybdenum-93. Of the limited number of reactions leading to this state, only the ^{93}Nb(p,n)^{93}Mo* and the ^{93}Nb(d,2n)^{93}Mo* reactions have to date shown an appreciable yield[1-3]. Irradiation of molybdenum with pile neutrons failed to yield any evidence of the reaction ^{92}Mo(n,γ)^{93}Mo* (ref. 4). Similarly, irradiation with 23-MeV. bremsstrahlung from a betatron indicated negligible cross-section for the (γ,n) reaction[4]. However, the (n,2n) reaction[5] did give some yield.

We have irradiated a molybdenum foil at 22 MeV. in our betatron beam and obtained the decay curve shown in the figure. The sample was irradiated close to the betatron target with a total of 12,000 r. delivered in a time short compared to 6·7 hr., and was then counted in large-angle geometry.

Though no 6·7-hr. activity was observed, the accuracy of our measurements allows us to estimate that no more than 20 counts/min. could be attributed to a 6·7-hr. half-life decay. From this we conclude that the integrated cross-section for the ^{94}Mo(γ,n)^{93}Mo* reaction is less than 0·06 MeV.-barn. (The value quoted by Duffield and Knight[4] obviously refers to the ratio of the 6·7-hr. to the 15·5-min. activities; we obtained 10^{-4} for this ratio.) According to (γ,n) systematics[5], this corresponds to a peak (γ,n) cross-section of less than 10 m.barn. In these calculations, we assumed the decay scheme of Kundu, Holt and Pool[3] and data of Goldhaber and Sunyar[6] and obtained the integrated cross-section by comparison with the activity from the ^{92}Mo(γ,n)^{91}Mo 15·5-min. reaction, the cross-section of which had been previously measured[7]. We estimate that less than 1/13 of the (γ,n) reactions in molybdenum-94 go to the isomeric state of ^{93}Mo.



Decay curve of molybdenum. Each point represents 60,000 counts. Insert shows points (open circles) obtained by subtracting 6·7-hr. and 15·5-min. activity from the measured values

An examination of the spins involved in the (γ,n) and other reactions leading to this isomer clearly indicates why negligible yield is obtained and explains why the (p,n) and the (d,2n) reactions on niobium form an exception, resulting in a good yield. The problem of the relative number of transition to the ground and isomeric states in a given reaction has been studied in this laboratory for a number of nuclei[7,8]. The results of these investigations may be used as a guide in this problem. In the table we have collected the data for each of the reactions pertinent to our present discussion.

REACTIONS LEADING TO ^{93}Mo* AND THE SPINS OF THE INTERACTING PARTICLES

Reaction	Initial nuclear spin	Total angular momentum carried in by reacting particle
^{92}Mo(n,γ)^{93}Mo*	0	1/2
^{94}Mo(γ,n)^{93}Mo*	0	1 (dipole transition)
^{94}Mo(n,2n)^{93}Mo*	0	≥ 3 on the average
^{92}Mo(d,p)^{93}Mo*	0	≥ 0
^{93}Nb(p,n)^{93}Mo*	9/2	≥ 1/2
^{93}Nb(d,2n)^{93}Mo*	9/2	≥ 0

According to Goldhaber and Hill[9] the ground state of ^{93}Mo is either $d^{5/2}$ or $g^{7/2}$, and the K/L internal conversion ratio for the isomeric transition seems to indicate an $E4$ transition. To explain the long half-life for such a high-energy isomer (2·4 MeV.), Goldhaber and Hill suggest the spin of the excited state may be 15/2 or more. In a recent communication[10] Goldhaber has shown that even a spin of 23/2 is admissible. Thus we are dealing with a nucleus of very high spin in the isomeric state and fairly large spin in its ground state.

In the case of (n,γ) thermal-neutron reactions, the intermediate ^{93}Mo compound nucleus has a spin of 1/2 at an excitation energy of about 7 MeV. We have previously shown that the cascade photons lead predominantly to the state of least spin-change[7,8]. Thus in the reaction ^{92}Mo(γ,n)^{91}Mo we have found that transitions from the intermediate state (spin 1, excitation energy ∼ 16–20 MeV.) to the isomeric state (spin 1/2) are favoured 5 to 1 over transitions to the ground state (spin 9/2). In ^{91}Mo the spin of the excited state is intermediate between that of the ground and isomeric states, whereas in ^{93}Mo the excited state has a spin lower than even the ground state. Thus transitions to the isomeric state are improbable. This is particularly true since only a few cascade photons are involved in thermal-neutron capture[11].

It has been shown previously[8] that the neutrons in (γ,n) reactions at the energies involved carry out an average of angular momentum of 1/2. Thus even in the most unfavourable case the intermediate ^{94}Mo compound nucleus spin will not exceed 5/2. Again, it will be seen that transitions to the isomeric state are not favoured. In the (n,2n) reaction we would expect[9] intermediate nuclear spins which are larger than for the cases just discussed, and the observed (small) ^{93}Mo* activity from this reaction is not unexpected. It can be readily seen from the table that the (*d*,*p*) reaction is certainly not more promising than the (*n*,2*n*) reaction and probably less.

So far, only reactions have been considered in which the initial nucleus had zero spin. For (*p*,*n*) and (*d*,2*n*) reactions the initial ^{93}Nb nucleus has a spin of 9/2. The resulting higher spin intermediate states which are thus obtained favour transitions to the isomeric state. For example, even if we assume *s*-state protons and neutrons in the (*p*,*n*) reaction, intermediate states of spin 7/2(0·20), 9/2(0·47) and 11/2(0·33) will be formed, with the weight of each spin shown in brackets. This shows clearly why the ^{93}Mo* state is reached in these two reactions and not in the others.

Spiral Morphology of Boron Particles

In recent work on the ultimate analysis of decaborane[1] the permeability of palladium to hydrogen was utilized to separate the elements formed in the pyrolysis of this compound. Decaborane, contained in sealed palladium capsules, was decomposed by heating at 900° C., leaving a solid pyrolysis residue of boron containing approximately 0·5 atom per cent palladium. The residue was in the form of hard, shiny black granules (0·5–1·0 mm.), the X-ray diffraction pattern of which consisted of three diffuse rings.

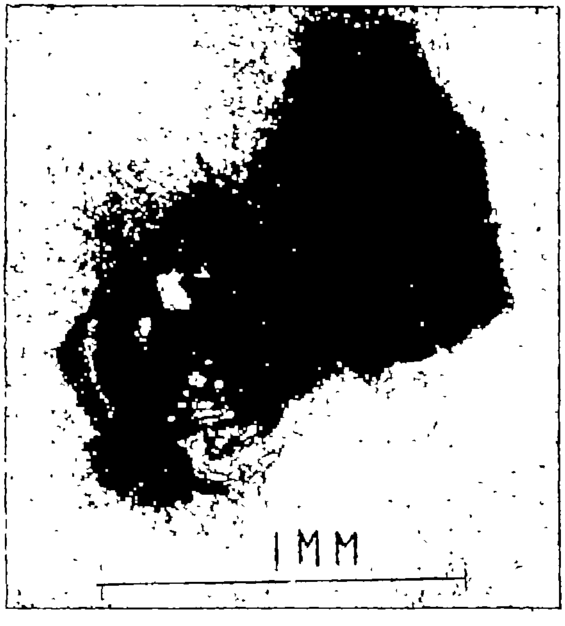

Fig. 1. Boron particles from pyrolysis of decaborane

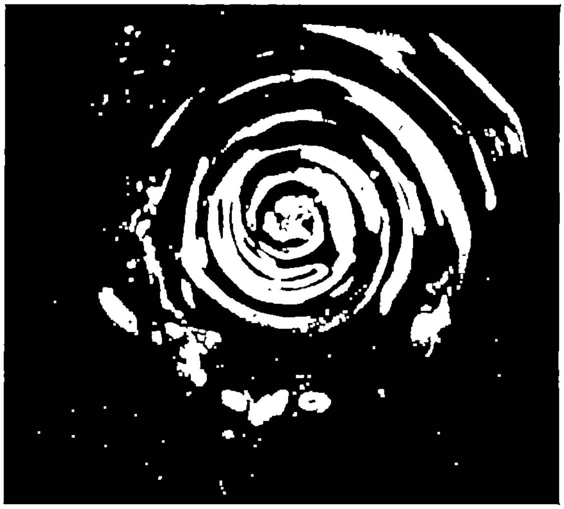

Fig. 2. Boron particle from pyrolysis of decaborane (dark-field illumination. × 80)

Microscopic examination disclosed that many of the particles possessed an external spiral morphology, as shown in Fig. 1. This is more clearly seen in the photomicrograph (Fig. 2) prepared by Dr. F. H. Horn, of this laboratory. The spiral lacked the sharp step heights usually observed in the spiral growth patterns of crystalline materials. It more closely resembled a rolled-up rug viewed end on.

At present we can offer no conclusive mechanism for the growth process which produced this unusual external morphology unaccompanied by any X-ray crystallinity. Pyrolysis of anthracene under the same conditions produced a non-crystalline carbon residue with no regular external structure.

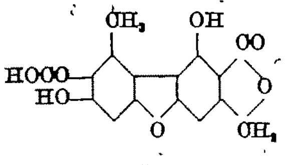
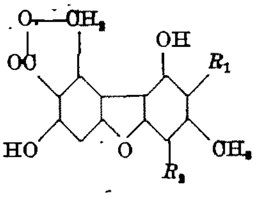
Structure of Porphyrilic Acid

Porphyrilic acid, a sparingly soluble acid of high melting point (approx. 298° after darkening from 270°), was isolated by Zopf[1] from the crustaceous lichens *Haematomma porphyrium* (Pers.) and *H. coccineum* (Dicks.). Both lichens contained other acids, the latter, for example, (—)usnic acid. Porphyrilic acid, for which no analyses were given, was characterized by an intense indigo-blue colour reaction with ferric chloride and a green colour with a solution of bleaching powder. On thermal decomposition, porphyrilic acid yielded a characteristic product, porphyrilin.

An acid, undoubtedly identical with porphyrilic acid, has now been isolated together with lævorotatory usnic acid from a lichen material consisting essentially of *H. coccineum*. The acid is extremely sparingly soluble in most organic solvents and is conveniently purified through its cyclohexylamine salt,

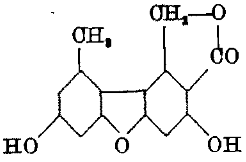


I



II R_1=COOH R_2=H

III R_1=H R_2=COOH



IV

$C_{16}H_{10}O_7 . C_6H_{11}NH_2$, m.p. 274–278° (decomp.). The acid crystallizes with one molecule of water ($C_{16}H_{10}O_7.H_2O$). When heated to the melting point (about 280°) it looses carbon dioxide, and porphyrilin (m.p. about 300° with sublimation)—$C_{15}H_{10}O_5$—is formed. It crystallizes with one mole of water and gives the blue ferric chloride reaction.

The presence of a carboxyl group in porphyrilic acid is indicated by the composition of the cyclohexylamine salt and of porphyrilin. Porphyrilic acid and porphyrilin contain one C—CH_3 group but no methoxyl groups. The acid gives a diacetate $C_{16}H_8O_5(OCOCH_3)_2$, m.p. 262–265° (decomp.), and on methylation with diazomethane yields methyl O-dimethyl porphyrilate, $C_{15}H_7O_3(OCH_3)_2COOCH_3$, m.p. 270–272°, which may be hydrolysed to O-dimethylporphyrilic acid, $C_{15}H_7O_3(OCH_3)_2COOH$, gradually decomposing from about 325°. Porphyrilin yields a dimethylether, $C_{15}H_8O_3(OCH_3)_2$, m.p. 267–269°. Hence both porphyrilic acid and porphyrilin contain two phenolic hydroxyl groups. Both compounds couple with diazotized amines to red azo dyes. Hydrolytic titration of O-dimethylporphyrilic acid indicates the presence of a lactone group. These facts account for six of the seven oxygen atoms in porphyrilic acid. Since the substance exhibits no carbonyl functions the remaining oxygen atom must be present as an ether link.

An insight into the carbon skeleton of porphyrilic acid was gained by degradation of O-dimethylporphyrilic acid. Oxidation with permanganate afforded a tetracarboxylic acid, $C_{12}H_2O(OCH_3)_2(COOH)_4$ (tetramethyl ester m.p. 221–223°), which when heated gave a yellow dianhydride, $C_{12}H_2O(OCH_3)_2(C_2O_3)_2$, m.p. about 330–335° with sublimation. On boiling with strong hydrobromic acid, the dianhydride underwent demethylation and partial decarboxylation to a dihydroxy dicarboxylic acid, characterized as the tetramethyl derivative, m.p. 149–150°. The acid was further decarboxylated by heating with quinoline and a copper chromite catalyst to a phenol *A*, $C_{12}H_8O_3$, m.p. 162·5°–164° (diacetate m.p. 141–142°).

Considering the predominant role of orcinol in lichen chemistry the most probable structure of *A* seemed to be either 3.7-dihydroxy-, 1.9-dihydroxy- or the unsymmetrical 1.7-dihydroxy-dibenzofuran. The two first substances are known, m.p. 241° and 215° respectively. The hitherto unknown unsymmetrical substance was prepared by mixed Ullmann coupling of 2-iodoresorcinol dimethylether and (excess) of 4-iodoresorcinol dimethylether. All three tetramethoxy-biphenyls were isolated. The 2,6,2′,4′-tetramethoxy biphenyl, m.p. 106–107°, was demethylated (HBr) with simultaneous elimination of one molecule of water and formation of 1.7-dihydroxydibenzofuran, m.p. 163–164·5° (diacetate m.p. 141–142°). The synthetic substance and its diacetate were identical with *A* and its diacetate (mixed m.p.).

From these results and the above genetic considerations, porphyrilic acid very probably possesses either structure I, II or III. These formulæ all account for the colour reaction with ferric chloride and for the easy decarboxylation to porphyrilin. However, porphyrilic acid but not porphyrilin forms a borate complex, as indicated by a comparison of the R_F value on borate-impregnated[3] and phosphate-impregnated paper of *p*H 8·7 (R_F = 0·03 and 0·15; 0·69 and 0·72 respectively, *n*-butanol–water). This indicates the presence of a hydroxyl group in the *ortho* position to a carboxyl group in porphyrilic acid, and structure III is therefore less probable.

Porphyrilic acid, undoubtedly, is formed in Nature by unsymmetrical oxidative coupling of simple phenols of the orsellinic acid series. Porphyrilin is an isomer of strepsilin[2] (IV), which also gives a blue ferric chloride reaction as well as green colour with bleaching powder and is a derivative of the symmetrical 3.7-dihydroxy-dibenzofurane.

A detailed account of this work will appear shortly in *Acta Chemica Scandinavica*.

New Molecular Compounds of Graphite

THE only molecular compounds of graphite previously reported in the literature are the graphite–ferric chloride compound, described by Ruedorff and Schulz[1], the compounds of graphite with chromyl chloride and chromyl fluoride reported by Croft and Thomas[2], and the compound with aluminium chloride noted by Croft[3]. This communication records the successful preparation of many new compounds of the same type.

Crystalline flake graphite with the size range minus 65 plus 100 mesh was heated with an excess of test substance, usually in a sealed tube. The procedure for heating and for detection of reaction necessarily varied from substance to substance: details will be published elsewhere.

Results, together with those for chlorides previously known to react and marked by an asterisk, are summarized in the accompanying table. By non-intercalation is meant that less than 0·5 per cent of the test substance was detected by analysis in the treated graphite.

The specificity shown by graphite in compound formation is remarkable. It was found that either a substantial quantity (15–83 per cent by weight in a compound) or none at all of a test substance could be intercalated. With the exception of iodine and boron, chlorides of non-metals were not occluded. This indicated that covalency of a substance is not a prime requisite for its intercalation in graphite. The successful intercalation of the chlorides of iodine

* Normally unstable, but stable when intercalated in graphite.
† Previously known to react.

is attributed to the considerable electron affinities of these compounds. Among the metal chlorides tested, only those in which the cation normally exhibits multivalence and which were in their higher valence states were intercalated. Thus $SbCl_5$, $BiCl_4$, $PtCl_4$ and $CuCl_2$ were readily intercalated; but the lower chlorides $SbCl_3$, $BiCl_3$, $PtCl_2$ and Cu_2Cl_2 did not react with graphite over a wide range of conditions. The intercalated chlorides of aluminium, gallium, indium, thallium, yttrium and zirconium were, unlike the other chlorides, hydrolysed *in situ* by washing, suggesting a distinct sub-group in the above list of molecular compounds.

Since multivalence is associated with an electronic configuration generally involving unsaturated penultimate electron shells, it is likely that these molecular compounds of graphite owe their existence to the transference of electrons from the incompletely filled bands of graphite to the intercalated metallic cations. This transfer would occur when the cations possess their maximum electron affinities, as in their higher valence states. Thus one would expect paramagnetism to be a good criterion of the possibility of intercalation. A good correlation was found to exist between paramagnetism of the test substance and successful intercalation in graphite. This theoretical treatment has been developed in some detail and appears to offer a satisfactory explanation for the formation and stability of molecular compounds and also a basis, of particular value from an applied point of view, for predicting the specificity of graphite for certain chlorides. One conclusion derived from the theory is that it should be possible to form molecular compounds of graphite by allowing the latter to react with paramagnetic salts other than halides. I have confirmed this conclusion for the sulphides CuS, FeS_2, V_2S_3, Sb_2S_3 and the oxides Sb_2O_5 and MoO_3. The successful intercalation of CrO_2Cl_2 and CrO_2F_2 noted by Croft and Thomas[2] also supports this conclusion.

A more detailed account of these investigations will be published elsewhere.

I am grateful to Mr. R. G. Thomas and Dr. A. L. G. Rees for advice and also to Mr. L. J. Rogers for assistance.

'Leuco-cyanidin' and Epicatechin

Bate-Smith and Swain[1] have recently come to the conclusion that the so-called condensed, 'catechin', tannins are in many instances identical with the 'leuco-anthocyanins' described by Robinson and Robinson[2]. Recent work here has suggested that the catechins and 'leuco-anthocyanins' are extremely closely related.

A 'leuco-cyanidin' has been isolated from cacao beans which moves as a single discrete spot when chromatographed in amyl alcohol - acetic acid, *n*-butanol – acetic acid, phenol or distilled water[3]. When heated for several minutes with 10 per cent hydrochloric acid, although cyanidin was produced, the main product was a reddish-brown precipitate, as found by Bate-Smith and Swain[1]. Numerous other polyphenols could be detected by paper chromatography and the reaction is obviously very complex.

Although leuco-cyanidin is stable in water at 100° C. for 3 hr., with 0·1 *N* hydrochloric acid for 5 min. at 100° C. an extremely interesting change takes place, as shown in Fig. 1. A catechin (*E*) and a reddish-brown precipitate (*P*) were the main products. The product (*E*) gave all the catechin colour reactions[4] and moved with identical R_F to (–) epicatechin in all four solvents, and on extraction from the paper and boiling was partly isomerized to a substance indistinguishable from (–) catechin on chromatography[5]. By quantitative chromatography[6], it was estimated that, of the leuco-cyanidin changed, 31 per cent (–) epicatechin and 6 per cent (–) catechin was formed. Further heating does not give increased yields due to condensation. No sugars were liberated.

When (–) epicatechin was treated under identical conditions 64 per cent was unchanged, and 16 per cent of (–) catechin had been produced by isomerization, as well as polymerized material. The conversion to (–) epicatechin, taking into account the subsequent epimerization and polymerization, is therefore of the order of 50 per cent. The nature of the (*X*) fraction (see Fig. 1) is unknown. The other major product is a reddish 'phlobaphene' (*P*) which is precipitated on standing. A search was made for milder conditions of hydrolysis; 1 per cent (w/w)

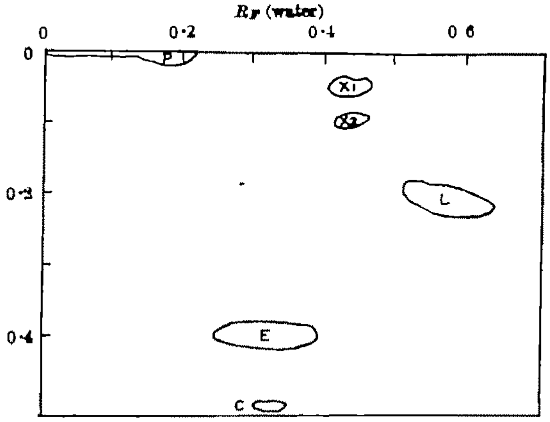

Fig. 1. Chromatogram of 1 per cent solution of leuco-cyanidin in 0·1 *N* hydrochloric acid after heating for 5 min at 100° C. The chromatogram was run first left to right with water as solvent, and then downwards with amyl alcohol – acetic acid (25° C.). Polyphenols detected with ferric chloride – potassium ferricyanide. Key to polyphenols: *L*, leuco-cyanidin; *E*, (–) epicatechin; *C*, (–) catechin; X_1X_2, unknown; *P*, condensed red pigment

oxalic acid at 100° C. for 5 min. in water or alcohol caused a similar conversion, as did 0·1 N acetic acid when heated for 1 hr. at 100° C. The reddish 'phlobaphene' and the (X) fraction were formed in every case.

These findings indicate an extremely close relationship between (–) epicatechin and a moiety of the leuco-cyanidin molecule. They suggest that the production of cyanidin in strong acid is probably due to a side reaction between two parts of the molecule, and the name 'leuco-anthocyanidin' is a misnomer.

It is hoped to publish this investigation in full detail shortly.

Gradient-Elution Analysis in Inorganic Paper Chromatography

WE have recently read with great interest the account of gradient-elution analysis to the International Analytical Congress[1]. This type of elution with a continuously changing solvent appeared to be of special value for separations of metal ions in butanol containing hydrochloric acid, as the R_F values change considerably from low to high acid concentrations.

In the investigation described here, the apparatus employed was even simpler than that for column separations. A large chemical jar 30 cm. high was used as development chamber for ascending development. The first solvent, in this case butanol saturated with 1 N hydrochloric acid (100 ml.), was poured into the bottom of the chamber and agitated with a magnetic stirrer. The chromatogram was then stood at the bottom of the chamber and the second solvent (here concentrated hydrochloric acid) added from a burette which was fixed through a hole in the cover of the jar.

The rate of addition of solvent was in relation to the speed of development. Each centimetre was first marked on the paper and the hydrochloric acid added in eleven 2-ml. portions for each of the first 11 cm. ascended; then, as the yellow ferric iron spot appeared to move too slowly, the rate was increased to 4 ml. per cm. for another 4 cm. of development. In all, the solvent ascended 15 cm. in about four hours.

Fig. 1 shows the spots obtained for ferric iron, cobalt and for a mixture of thallium, mercury, cadmium, bismuth, iron, nickel, copper and cobalt. The last-mentioned mixture was completely resolved into eight well-separated spots, which is impossible to achieve with any simple mixture of butanol and hydrochloric acid so far described.

One defect of gradient elution analysis was noted with respect to ferric iron. Ferric iron has R_F 0·1 in butanol saturated with hydrochloric acid, 0·4 in butanol saturated with 3 N hydrochloric acid and 1·0 in butanol – 30 per cent concentrated hydrochloric acid.

As shown in the photograph, gradient elution produces a long 'comet'. This is formed also when more or less hydrochloric acid is added to the butanol solvent. We suggest that comet formation is due to the fact that the ferric ion in hydrochloric acid exists as the following complexes in equilibrium:

Fig. 1. From left to right: ferric iron with comet, cobalt, a mixture containing thallic (fastest), mercuric, cadmium, bismuth, iron, nickel, copper and cobalt (slowest) ions. The black specks are due to rust which was accidentally introduced from a fume chamber used for drying the chromatogram. All elements were detected by spraying with a solution of ammonium sulphide

$$FeCl^{++} \rightleftharpoons FeCl_2{}^{+} \rightleftharpoons FeCl_3{}^{\circ} \rightleftharpoons FeCl_4{}^{-}.$$

The un-ionized form would certainly be the most solvent-soluble; hence, if the gradient of hydrochloric acid approached the ferric ion spot so as to form $FeCl_3{}^{\circ}$ at its front, but with a little higher concentration of acid the anion $FeCl_4{}^{-}$ is formed, then the movement of the lower portion of the spot will be more and more retarded, thus forming the comet. This type of comet could also form with other elements which exist in such equilibria; however, a certain critical gradient appears to be necessary for comet formation, as, for example, mercuric and thallic ions form round spots.

There appear to be numerous solvent systems in inorganic paper chromatography where gradient elution would improve separations; work on some of these is in progress.

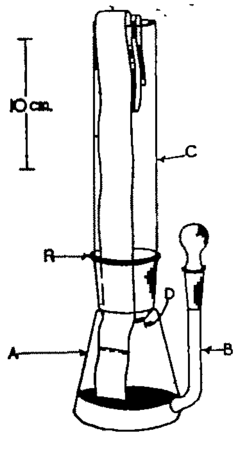
Two-dimensional Paper Chromatography of Radioactive Substances

AN automatic scanning technique employing a Geiger–Müller tube for the location and estimation of radioactive substances separated on unidimensional paper chromatograms has been described[1]. The application of this technique to two-dimensional chromatograms is tedious because a large sheet of paper has first to be cut up into the equivalent number of unidimensional strips and each strip scanned separately. To obviate this difficulty, an alternative technique to the conventional form of two-dimensional paper chromatography has been



successfully developed for the application of two or more solvent systems to the same labelled mixture.

In the conventional technique[2], the mixture is partly resolved by running with the first solvent in a direction parallel to one edge of a square sheet of paper. The paper is then turned through a right-angle and run with a second solvent. The separated substances are finally located by treating the paper with a suitable reagent. If, however, the components separated in the first solvent could be located accurately at that stage without decomposing them, then only those parts of the paper containing these components need be developed in a second solvent. With radioactive components, this can, in fact, be done by the scanning techniques already mentioned. The problem then is to concentrate these components, or better still only those components known to be further resolvable, by running with another solvent, on to a second strip of paper so that it can be run in a second solvent under unidimensional conditions. This may be done readily by the following method.

The boundaries of the radioactive zones separated unidimensionally in the first solvent are lightly marked off in pencil while the strip is being scanned radiometrically[1]. The corresponding sections of paper are then cut out and attached by means of a stainless steel pin to the bottom of a new strip. Each strip is then wedged lightly between the ground-glass surfaces of the *B*-50 neck of the empty elution unit illustrated. The unit consists of a flat-bottomed flask *A* provided with a side-tube and stopper *B*. The extended *B*-50 cone is sealed off at the lower end *D* so that the flask is closed. The strip is adjusted so that the attached section hangs to within 1 cm. or so from the bottom of the flask. One unit of the size illustrated will accommodate four 1-in. strips equally spaced around the joint. The eluting solvent (which must be volatile) is then added through *B* until the section is immersed to a depth of about 1 mm. The solvent rapidly ascends the strip until it emerges just above the rim *R*, when it is no longer in equilibrium with its own vapour. It therefore evaporates and the eluted substance becomes concentrated in a narrow band (about 0·5 cm.) at the solvent front which is on the new strip of paper. *C* is gently removed, the section detached and the concentrated zone chromatographed in the second solvent and finally scanned. Evaporation may be aided by placing the unit in a gentle air stream (for example, fume cupboard draught). When an acid – water – alcohol mixture was used for concentrating phosphate esters labelled with phosphorus-32, elution was complete and quantitative within a few hours and contamination of the ground-glass surfaces was negligible. Even in still air at 0° C. (conditions used for handling unstable esters) the solvent front rarely ascended more than 2–3 cm. above *R*. Subject to the chemical stability of the substances, the whole process can be repeated, thus effecting 'multidimensional' chromatography. The method also proved to be useful for concentrating the material of several paper sections (three or four attached to one strip) until sufficient was obtained for chemical tests.

Reduction of Liquid Flow in Paper Electrophoresis

INTERPRETATION of the results of paper electrophoresis[1-3] is complicated by liquid movement in the paper, due to hydrostatic flow, attainment of equilibrium in the paper, and electro-osmosis. Hydrostatic flow, due to the difference in level of buffer in the electrode vessels, can be eliminated by arranging a siphon between the vessels[1].

Liquid flow has been further examined in this laboratory with the object of identifying the underlying factors and minimizing their effects, using the apparatus of Woods and Gillespie[2], which is a modification of that described by Cremer and Tiselius[1]. With this arrangement, movement of liquid due to evaporation from the paper is minimized by clamping the paper between glass plates; but liquid flow due to other factors is considerable. Movement of spots of trinitrobenzene and *o*-nitroaniline has been used for following liquid flow. At *p*H values of 5·0 and below, trinitrobenzene is uncharged and its position is determined by spraying with 5 per cent dimethyl aniline in ethanol which produces a pink colour, intensified by exposure to ammonia gas. At *p*H 7 and above, *o*-nitroaniline is uncharged and forms a yellow spot.

In the initial experiments, after soaking the strip in buffer and blotting it between filter papers[1,3], three spots of the indicator solution were applied, one at the centre and the other two 8 cm. on either side. In the absence of an applied potential difference, considerable inward flow of buffer solution from each end was observed, even when the edges of the two glass plates were sealed, due to the unsaturated condition of the paper. Thus, on electrophoresis, the apparent mobilities of spots moving from the centre of the paper would be low.

By applying the spots prior to wetting the paper, allowing most of the indicator solvent to evaporate, then saturating the strip with buffer and, without blotting, immediately clamping it between the glass plates, no appreciable spreading of the spots occurred. Moreover, by sealing the plates along the edges and binding them transversely with adhesive cellulose tape, evaporation was reduced and fairly uniform flow was observed throughout the length of the sealed region of the strip when the current was passed.

The use of buffer-saturated paper completely arrested inward flow from the ends and replaced it by a very slight outward flow due to evaporation of the buffer from the exposed ends of the strip. When proteins were applied to the paper before saturation with buffer, they were adsorbed more strongly than were the indicators. This effect was avoided, without altering the liquid flow, by spotting the protein solution on the buffer-saturated strip at a locally blotted site.

Electro-osmotic flow is due largely to the migration of hydrated cations which dissociate from the carboxyl groups of the paper. A corresponding but much smaller effect occurs at the glass – water interface. With an acidic or negative paper the liquid moves towards the cathode, and with a basic or positive paper it would be expected to flow towards the anode. Tiselius[4] recently reported that negative and positive papers had been prepared in his laboratory by Perath and Flodin for use in paper electrophoresis, using 2-amino-ethyl sulphuric acid for the latter. We have prepared basic paper by immersing strips of 3 *MM* Whatman paper in 0·1 *M* periodic acid at room temperature to form dialdehyde groups in the paper, which are then coupled with hydrazine derivatives. The periodate-treated paper is washed in tap water for 30 min. and immersed in a 10 per cent solution of Girard's *P* reagent[5] (pyridinum acethydrazide chloride) in a mixture of 9 vol. of ethanol and 1 vol. glacial acetic acid at 70° C. for 30 min. and again washed in running water. The amount of the Girard's reagent reacting with the paper is determined by the time of treatment with periodic acid (Table 1). Aminoguanidine and 2-aminoethylhydrazine[6] have also been coupled to paper in this way.

Table 1

Time of periodic acid treatment (min.)	0	10	30	60
Nitrogen content of paper (per cent) on treatment with Girard's *P* reagent	0·022	0·030	0·037	0·057

Untreated paper contained 0·008 per cent nitrogen.

The contraction in length of the papers during treatment was less than 1 per cent, and there was neither thickening, discoloration nor any noticeable reduction in wet strength.

The cathodic flow of liquid in untreated paper increased with *p*H, corresponding with increased dissociation of the carboxyl groups. In order to prevent electro-osmotic flow as the *p*H of the buffer was raised, it was necessary to lengthen correspondingly the initial treatment with periodic acid. Paper oxidized with periodic acid coupled with aminoguanidine was positive at and below *p*H 5; at *p*H 7 and above this value the flow was the same as in untreated paper. Treatment of the paper with periodic acid alone for periods up to 40 min. increased the acidity only slightly as determined by electro-osmotic flow. However, oxidation with bromine and alkali[7] produced a more strongly acidic or negative paper, with marked cathodic flow at *p*H values of 4 and above. At *p*H 2 no flow was observed, due, presumably, to suppression of ionization. An even more strongly negative paper, prepared by coupling paper oxidized with periodic acid with phenylhydrazine *p*-sulphonic acid[8], revealed no change in the cathodic flow even when the *p*H of the buffer was reduced from 8 to 2. The buffers employed were: *p*H 2, 4 and 5, 0·1 *M* acetate; *p*H 7, 0·1 *M* phosphate; *p*H 8, 0·04 *M* veronal hydrochloride; *p*H 9, 0·1 *M* glycine.

The acidic or basic nature of the treated papers was further evidenced by the uptake of the basic dye methyl green or the acidic dye naphthol green respectively, when the papers were immersed in an aqueous solution containing both dyes and then washed in water. After similar exposure to the mixture of dyes, untreated paper retained only a slight basic stain. These ion-exchange properties are in keeping with previously described experiments on chemically modified cotton cellulose[9].

The charge on the paper used in electrophoresis experiments not only affects the overall mobilities as a consequence of electro-osmosis, but it also causes ions of opposite charge to be adsorbed. Thus when using untreated paper, which carries a slightly negative charge, any protein components migrating cathodically tend to trail, and inferior separations of mixtures are obtained. We have observed this effect with the components of horse-radish peroxidase[10] and found a marked change in the electrophoretic pattern on changing from untreated to positively charged paper.

It is probable that neutral or positive paper may also be of value in the chromatography of basic substances which normally trail due to adsorption.

Gas Content and Electrolytic Etching Behaviour of Aluminium

If aluminium is etched in an electrolytic cell, with a 0·2 *N* sodium chloride solution as the electrolyte, at a temperature of 90° C., and using current densities of 0·1–0·2 amp./cm.², different patterns of attack may be observed with different samples of aluminium. The latter, which were in the form of rolled foil, were all of a similar nominal purity grade—sold as "99·8% Al"—and were given an identical etching treatment. With some of them the attack was widespread over the whole surface, while with others it was strongly localized, producing deep pits, with large parts of the surface remaining unattacked. Acid or alkaline cleaning treatments, applied before the electrolytic etch, failed to alter the general picture, that is, it was still possible to distinguish between the two types of attack.

No correlation between the metallic impurities of the samples and their etching behaviour was found. However, when the aluminium was heated to 600° C. for not less than one hour, blistering occurred with some samples, and a strong correlation was found between the blistering and the etching behaviour. Those samples most prone to blistering were also those in which localized etching and pitting was observed.

It is emphasized that the etching behaviour referred to is that shown by the foil before heating. No blistering or internal cavities could be observed when examining cross-sections of the unheated foils under the microscope; thus the localized attack is not the result of the linking up of cavities already in existence.

It is known that blistering in heat-treated aluminium is due to hydrogen; hence it would seem that the etching behaviour is correlated with the hydrogen content of the aluminium, in the sense that the higher the hydrogen content the more localized the attack. For example, very severe localized attack will occur in a specimen which, on heating, gives a cavity to metal ratio of 0·04.

A Cytochrome Peroxidase from *Pseudomonas fluorescens*

A CRUDE extract of *Pseudomonas fluorescens* was found to oxidize a reduced dye, 2,6-dichlorobenzenoneindo-3′-chlorophenol. The activity in the crude extracts seemed similar to the 'dye oxidase' activity described by Smith and Stotz in plant tissues[1]. On partial purification, the 'dye oxidase' activity was always associated with a pigmented component. Spectral analysis of this pigment in the reduced and oxidized state indicated that it had an absorption similar to the respective states of cytochrome *c*. However, this pigment is not reduced by reduced triphosphopyridine nucleotide using purified triphosphopyridine cytochrome *c* reductase obtained from liver[2].

Additional evidence suggesting a difference between animal cytochrome *c* and this pigment was found by placing a mixture of the two on an 'Amberlite *IRC*-50' column in 0·1 *M* phosphate buffer at *p*H 7·5, according to the method of Neilands[3]. The animal cytochrome *c* formed a sharp red band whereas the bacterial pigment, along with most of the 'dye oxidase' activity, passed through the column. Furthermore, reduced cytochrome *c* added to the bacterial extracts is not oxidized under the same conditions in which the bacterial pigment is oxidized.

The reduced pigment was found to be oxidized by hydrogen peroxide, suggesting a cytochrome *c* peroxidase mechanism. Addition of hydrogen peroxide to the extracts and reduced dye carried the oxidation of the dye to completion (see Fig. 1, curve *A*). The 'dye oxidase' activity, observed in the absence of added hydrogen peroxide, was found to be due to hydrogen peroxide formed on reduction of the dye by hydrogen gas using palladium–asbestos as catalyst, as the addition of catalase inhibited completely the reaction (curve *B*). The reduced dye acts chemically with the pigment, giving the oxidize dye and reduced pigment respectively.

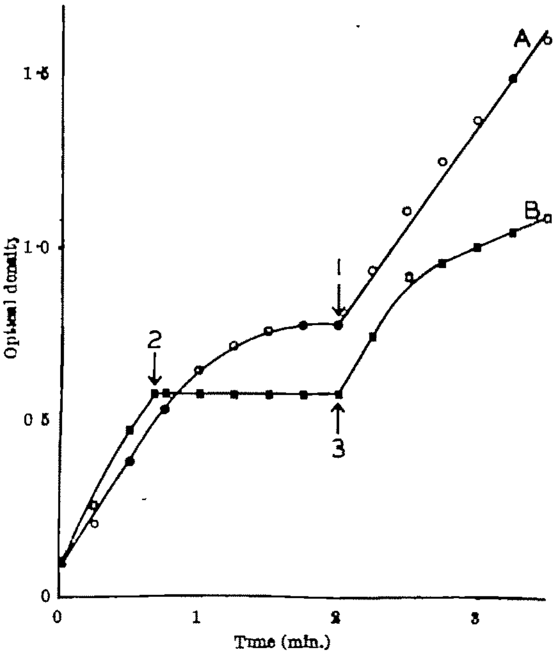

Fig. 1. All values are measured at 575 mμ. The reaction mixture consists of 0·01 c.c. of the crude extract, 2·3 c.c. of the reduced dye, and 0·1 *M* orthophosphate buffer at *p*H 7·5 to bring the total content to 3·0 c.c. The additions are, respectively: (1) 2 μ*M* hydrogen peroxide; (2) 1 mgm. Armour catalase; and (3) 10 μ*M* hydrogen peroxide

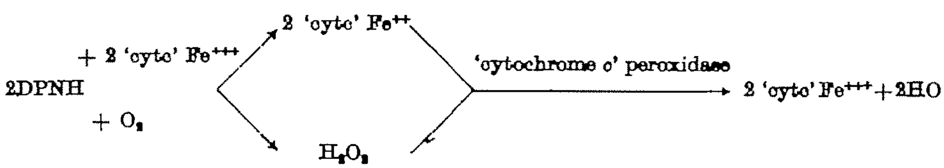
Reduced diphosphopyridine nucleotide (DPNH was oxidized at a fairly rapid rate in the bacterial extracts with a trace of dye, which was needed to link the diaphorase with the pigment. Addition of hydrogen peroxide increased the rate of disappearance of the reduced nucleotide. This suggested that the organism would utilize two moles of reduced diphosphopyridin nucleotide: one reducing the pigment, and the second reacting with oxygen to form hydrogen peroxide. These would then react in a peroxidati reaction yielding the oxidized pigment and wate Therefore, the following reaction scheme suggestin a physiological function for cytochrome *c* peroxidas is proposed:



Adaptation experiments provided more evidenc supporting the above scheme. When the organism was grown under low oxygen tension, it was found to have a large amount of the pigment, peroxidas activity and catalase activity, and a moderate amoun of diaphorase activity. Under high oxygen tension only a trace of the pigment was observed, no peroxidase activity was found and the catalase activit was reduced, whereas the diaphorase activity increased (see Table 1). This suggests that under hig oxygen tension a non-cytochrome system is in operation. At lower oxygen tension, the cytochrome syster

functions primarily. The appearance of this cytochrome system appears to be adaptive to low oxygen tension. This would be in agreement with Theorell's observation that the reduced yellow enzyme reacts with oxygen under high oxygen tension to form hydrogen peroxide, and with cytochrome *c* under low oxygen tension[4]. Further details of the nature of cytochrome *c* peroxidase activity and its physiological significance will be described elsewhere.

Relation of the Permittivity of Biological Cell Suspensions to Fractional Cell Volume

As was first shown in work on the red blood cell[1], the high permittivity (of the order of thousands) of biological cell materials is the result of an electric condenser action originating in an extremely thin section—possibly a bimolecular lipid layer—of the surface envelope, in which the principal part of the cell resistance is located. Under certain conditions, the capacity of this 'membrane' condenser can be calculated[2] from the observed permittivity and has been found to be closely the same for certain types of cell, namely, about 0·9 μF./sq. cm., in the radio-frequency region[1,3-5], corresponding to a probable thickness of the membrane of about 30 A. This calculation can be carried through rigorously only when the number of cells in the material is small. The analysis of denser cell materials raises the question of the form of the relationship between permittivity (ϵ) and fractional cell volume (ρ) in a system exhibiting this type of dielectric mechanism. Although this problem has been given some theoretical attention in the past, the only experimental data now available are those obtained in my early work on dog erythrocytes[1].

	2a* (μ)	a/b*	C_m (μf/sq. cm.)	t_m/ϵ_m (A.)
▣, Dog erythrocytes in serum	7·8	4·2	0·82	10·7

●, *Saccharomyces cerevisiae* in 0·25 per cent sodium chloride (suspension approximately homogeneous in size, prepared from Fleischmann's yeast)	5·5	1	0·78	11·3

* 2a, 2b, axes of equivalent spheroid. Temp. 21·4° C.

The accompanying graph shows results on suspensions of other cell species. The method used in measuring the permittivity of such systems, which are good conductors, has been described[6]. The frequency was 16 kc./s., which is within the region of nearly constant permittivity of all these cells, being above the low-frequency dispersion region found in some of them and below the high-frequency dispersion region, which represents the effect of the impedance elements in series with the membrane capacity[1,4].

Each line on the graph represents measurements on a series of known dilutions of a concentrated suspension, the volume concentration of the samples withdrawn for dilution being controlled by their conductivities. In the study of the normal erythrocytes, the absolute values of ρ were determined with the hæmocrit, a small correction (2·5 per cent) being introduced to take into account the residual serum. With the other types of cell, ρ was calculated from cell number, measured with a hæmacytometer, and average individual cell volume, computed from the cell dimensions, measured microscopically.

The results can be summarized as follows. The form of an $\epsilon \sim \rho$ graph does not depend on the absolute size of the cell, but on the shape of the cell, although not to a very marked degree. The different spherical cells have all the same form of graph, which is not significantly different from that of the relatively rounded erythrocytes of sheep; but these graphs level off faster than does the graph for the very flat erythrocytes of dog and rabbit. The theoretical aspects of these results will be considered elsewhere.

In the legend are recorded also membrane capacity C_m (µf./sq. cm.) and ratio t_m/ϵ_m of membrane thickness to membrane permittivity of the cells, based on all observations now available and calculated from the initial slope of the $\epsilon \sim \rho$ graph by using the formula of ref. 2. The membrane is assumed to be the same over the whole surface of the cell and to have negligible ionic conductance. The strict validity of the latter assumption cannot be established by direct experiment, although observations on packed cells showed that the membrane conductance is certainly very small in all these cells (data on erythrocytes in ref. 5). The formula contains a form factor (g) which in the case of a normal erythrocyte was obtained by taking the cell to be equivalent to an oblate spheroid (axes $2a$, $2b$) of the same major axis ($2a$) and volume as the cell. The other cells were calculated as spheres, $g = 2\cdot25$. The value $2a$ is an appropriately calculated mean of the microscopically measured diameters of a representative number of cells.

With the exception of the lecithinated erythrocyte, there is no significant difference between the values of t_m/ϵ_m for these different types of cell, indicating that both thickness and permittivity of the membrane are closely the same in all of them. In the frequency region above the experimental frequency (16 kc./s.), the frequency dispersion of the permittivity of the membrane of all these cells is very small and possibly the same in all of them[3,4]. Since lecithination results in more pronounced dispersion in this region[6] the permittivity of the lecithinated erythrocyte membrane at 16 kc./s. is probably higher than that of the normal membrane. This appears to offer a satisfactory explanation of the rather low value of t_m/ϵ_m for the lecithinated cell, without the necessity of assuming that the thickness of the membrane is substantially altered.

Influence of Hypophysectomy and of Adrenocorticotropic Hormone on a Mammalian Adaptive Enzyme System

THE purification of a mammalian hepatic tryptophan peroxidase–oxidase system, and its properties, have been described by Knox and Mehler[1]. These authors demonstrated the system to be an adaptive one, increasing five- to ten-fold within 4–10 hr. following the intraperitoneal injection of massive doses of L-tryptophan[2]. That the adaptation is in fact real, with the increase in enzymatic activity resulting from a net synthesis of enzyme protein, has been discussed by Knox and Mehler[2], and also by Lee and Williams[3], who employed ethionine to inhibit the adaptation synthesis.

The important role of the pituitary in protein metabolism has been known for some time, and it was considered of interest to determine the effects of hypophysectomy on the ability of the rat to respond adaptively to injections of tryptophan. Normal male rats of the Long–Evans strain, weighing 120–140 gm., were used. Some animals were hypophysectomized at forty days of age, and were used four or fourteen days after operation, at which times their weights were in the range of the normal controls. All experimental animals were injected intraperitoneally with 0·7 m*M* L-tryptophan six hours before sacrifice. Controls were injected with saline. The rest of the experimental details follow the procedure of Knox[4].

The results presented in the accompanying table demonstrate the progressive failure of injected hypophysectomized animals to respond with an adaptive increase in the enzyme, although the static enzyme level is normal or greater than normal. By the fourth post-operative day, the injected animals give a response two-thirds of normal, and by the fourteenth post-operative day this response has decreased to one-third of the normal level.

Experimental group	µ*M* Kynurenin formed per gm. liver per hr.
Normal controls (15)*	1·59 ± 0·10†
Hypophysect. controls[a] (18)	2·05 ± 0·14
Hypophysect. controls[b] (6)	2·20 ± 0·13
Normal injected (10)	16·2 ± 0·9
Hypophysect. injected[a] (9)	11·1 ± 0·6
Hypophysect. injected[b] (10)	5·4 ± 0·6

* Number of animals in parentheses.
† Mean ± standard error.
a, 4 days post-operative.
b, 14 days post-operative.

These results, which indicate the relative inability of the hypophysectomized animal to synthesize this enzyme, could also be explained as a consequence of any of the following conditions in these animals: decrease in formylase activity, increase in kynureninase activity, absence of enzyme activators, presence of enzyme inhibitors, and a decrease in a peroxide-generating reaction necessary to initiate the reaction with tryptophan. All these possibilities have been eliminated by suitable combinations of liver homogenates from normal and hypophysectomized animals. Additionally, the failure of significant quantities of formylkynurenin, anthranilic or kynurenic acids to accumulate was shown by spectrophotometric measurements at their absorption maxima.

No differences were observed between normal and sham-hypophysectomized animals, either in their static or adaptive enzyme levels. That the relative failure in the response of the hypophysectomized animal was not due to an earlier or later response was demonstrated by determinations made at intervals of 3, 6, 10, 15 and 24 hr. after injection.

Knox[4] demonstrated that the pituitary–adrenal axis was concerned with non-specific increases (that is, increases following injection of inductors other than tryptophan) in the activity of the enzyme system, since these effects disappeared after adrenalectomy. However, the magnitude of the adaptive response of the adrenalectomized animal to tryptophan was the same as that of the normal animal given tryptophan. If this is correct, then it would be expected that injections of the adrenocorticotropic hormone should cause an increase in the static level of the enzyme. Normal animals were therefore injected with 20–30 U. of adrenocorticotropic hormone in gelatin six hours pre-sacrifice. Controls were injected solely with gelatin. A control value of $2 \cdot 15 \pm 0 \cdot 29$ μM kynurenin formed per gm. liver per hour was obtained in nine animals, whereas twelve animals receiving adrenocorticotropic hormone showed a level equivalent to $5 \cdot 11 \pm 0 \cdot 52$ μM. This increment was highly significant statistically.

Complete details of these and other experiments in which the role of pituitary hormones has been investigated will be reported elsewhere.

Extraction of a Heparin-like Substance from Mast Cell Granules in Mouse Connective Tissue

VARIOUS workers, Holmgren, Wilander, Jorpes and recently Ehrich *et al.*, have shown that there is a relationship between the number of mast cells and the amount of heparin in a tissue[1-4]. Confirmation was added by Oliver *et al.*, who were able to extract fifty times as much heparin from a dog tumour composed predominantly of mast cells as from normal dog liver[5]. The present work suggests the presence of a heparin-like substance in mouse mast cell granules.

A convenient method has been found for the selective extraction of mast cell granules from mouse connective tissue. The skin was separated from the trunk, pinned out and the exposed subcutaneous fascia dissected away. The fascial tissue from fifty mice so obtained was placed in 50 ml. of sterile distilled water in a sterile stoppered bottle and shaken for 1–2 hr. at a maximal speed with a 'Towers' shaker.

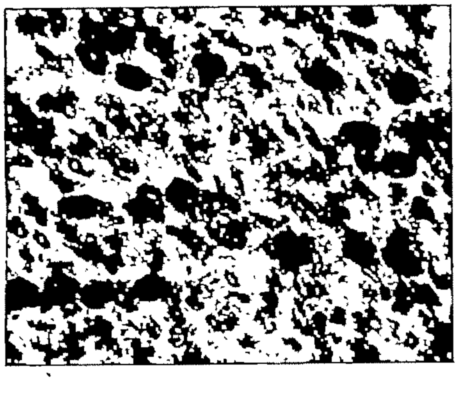

Fig. 1. Spread of subcutaneous connective tissue of a mouse, showing the normal mast cells and some free granules. Toluidine blue stain. (× c. 270)

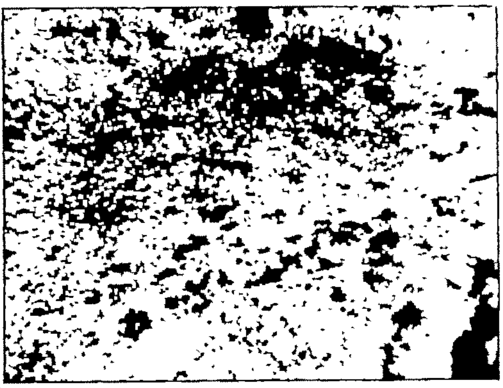

Fig. 2. Spread from the same tissue after shaking for 2 hr., showing a great number of free granules scattered throughout. Some disrupted mast cells can be seen near the top of the picture. Toluidine blue stain. (× c. 270)

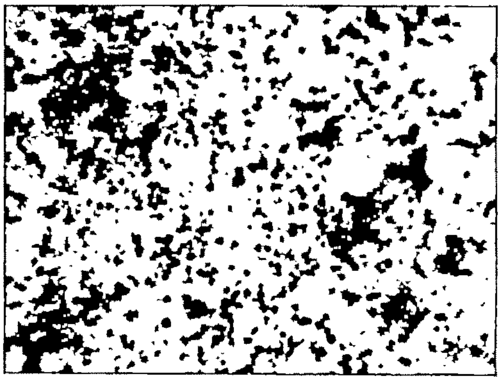

Fig. 3. Smear of the precipitate. Mast granules are seen of different size and shape. Toluidine blue stain. (× 570)

The fluid was removed with a sterile pipette and centrifuged at about 1,000 rev./min. for 10 min. The precipitate was found to consist predominantly of granules which stained metachromatically with toluidine blue (Fig. 3). Examination of the tissue after shaking showed that the majority of the mast cells were disrupted and, in addition to those granules which had been discharged into the fluid, others were diffusely spread throughout the tissue (Fig. 2).

No marked anti-coagulant effect was observed when the material containing the granules was added to fresh mouse blood. But after the material had been treated by the method for the extraction of heparin from tissues devised by Wilander[6], an anticoagulant effect was demonstrated. About 2·5 mgm. of dried extract was rendered from 0·20 gm. of moist granule preparation. 0·5 mgm. of that extract, dissolved in 0·1 ml. of distilled water, inhibited the coagulation of 0·25 c.c. of fresh mouse blood for

Table 1. COAGULATION TIMES AND CORRESPONDING QUANTITIES OF THE EXTRACT

Extract (mgm. in 0·1 c.c. distilled water)	Mouse blood (c.c.)	Coagulation times
0·5	0·25	<48 hr.
0·25	0·25	20 min.
0·12	0·25	13 min.
0·06	0·25	10 min.
0·03	0·25	8 min.

longer than 48 hr. This solution, diluted two-, four-, eight- and sixteen-fold and mixed with blood in the same proportion by volume, delayed coagulation for 20, 13, 10 and 8 min., respectively, but normal clotting took place in the presence of a × 32 dilution. Table 1 shows the coagulation times and corresponding approximate quantities of the extract. The substance extracted from the granules gave a metachromatic reaction with subsequent precipitation with toluidine blue. These observations strongly suggest a resemblance of the extracted material to heparin.

I am indebted to Prof. R. D. Passey and Dr. T. D. Day for their encouragement and help and criticism, and wish to thank Mr. J. B. Kirkham, who provided the photomicrographs.

Specificity of Complete Cold Auto-Agglutinins

Cold and warm auto-agglutinins exist. Both occur in the complete and incomplete forms. They are generally believed to be non-specific. Recently, doubt has been cast on their lack of specificity. I consider that (complete) auto-agglutinins might consist of multiple specific components[1-3]. Recently, Crawford, Cutbush and Mollison[4] have shown that incomplete cold auto-agglutinins present in all human sera have the specificity anti-*H*. The degree of sensitization of cells of various groups by these antibodies could be arranged in the following descending order, O—A_2—B—A_1—A_1B. Such reactions correspond to the relative amounts of *H* present in these various cells, *O* cells containing the most *H* and A_1B cells the least. Further, the action of incomplete cold auto-antibodies was inhibited by *H* substance, and their reactions closely agreed with those of an eel anti-*H* serum. Absorption of the antibodies in the cold by cells of various groups revealed that if A_1B cells are used the amount of antibody absorbed is inappreciable, whereas if *O* cells are used ability to sensitize group *O* cells or cells of groups A_1 and A_2 was completely abolished. These workers consider that the specificity of other non-specific antibodies needs to be re-examined. Davidsohn and Oyamada[5] have shown that the warm auto-agglutinins associated with hæmolytic anæmias are predominantly specific for the individual's own cells. Weiner *et al.*[6] have demonstrated that such an auto-agglutinin had the specificity anti-*e*.

The complete cold auto-agglutinins which are present in almost all Indian bloods were therefore re-investigated. For convenience *AB* bloods were examined as they do not contain iso-agglutinins. The sera were titrated against cells of groups A_1B, A_2B, A_1, A_2, *B* and *O*, and in each case against the patient's own cells. Typical results are reproduced in Table 1.

It is evident that the strengths of agglutination do not correspond to the expected amount of *H* agglutinogen in the various cells, and that these antibodies are not predominantly specific for the individual's own cells.

Table 1. Titres of Cold Agglutinins in an A_1B Serum against Various Cells at 4–6° C

Cells	Activity of undiluted serum	Titre
A_1B	+++	8
A_2B	W	2
A_1	+++	8
A_2	+++	16
B	+++	128
O	+++	16
Own	+++	32

The antibodies did not give parallel reactions with an anti-*H* serum prepared by absorbing the serum of the Indian water buffalo with A_1B cells (water buffalo anti-*H* is more powerful than that prepared from Indian cattle). *H* substance (dried saliva of a group *O Le* (*a-b-*) secretor) produced some inhibition of the action of these antibodies on various cells. Similar inhibition was produced by the saliva of a group *O Le* (*a-b-*) non-secretor. The secretor saliva successfully inhibited the water buffalo anti-*H* but the non-secretor saliva did not. In some sera complete absorption with *O* cells failed to abolish activity upon other cells, and similar findings in certain other sera were obtained after absorption with the individual's own cells. Elution of the antibody from the cells used for the absorption gave inconclusive results.

The titration and absorption experiments indicate that the complete cold auto-agglutinins present in the sera of most Indians do not give the reactions expected of anti-*H*. This view is supported by the examination of the titration values of these cold agglutinins in a number of sera undertaken in connexion with another investigation (to be published). In this investigation complete cold agglutinins in the sera of Indians of all groups were titrated in parallel against *O* cells, compatible *A* or *B* cells and the individual's own cells. The results are summarized in Table 2.

Table 2

1st Series	
Number of sera examined	10
Number of sera in which titres against *O* cells were higher than the individual's own	74
Number of sera in which the individual's own cells were agglutinated to higher titres than *O* cells	1
Number of sera showing equal activity against both *O* cells and the individual's own	
2nd Series	
Number of sera examined	81
Number showing highest titres against *O* cells	41
Number showing highest titres against compatible *A* or *B* cells	14
Number showing greatest activity against the individual's own cells	1
Number showing equal activity against all cells	1

While it appears that complete cold auto-agglutinins do not have the specificity anti-*H*, the possibility of anti-*H* being a component antibody cannot be excluded.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, October 19

Institution of Electrical Engineers (at Savoy Place, London, .C 2), at 5.30 p.m.—Discussion on "Television".

Institute of Metal Finishing (joint meeting with the Society ' Chemical Industry, Corrosion Group, at Burlington House, ccadilly, London, W.1), at 6.30 p.m.—Mr. H. A. Holden: "The osphating of Steel Prior to Painting"; Mr. J. F. Andrew, Dr. S. G. arke and Dr. E. H. Longhurst: "The Protective Properties of arious Phosphate Coatings on Steel".

Tuesday, October 20

University College, London (in the Anatomy Theatre, Gower reet, London, W.C.1), at 1.15 p.m.—Prof. J. B. S. Haldane, F.R.S.: he Physiology of Diving".*

Society for Applied Bacteriology (in the Lecture Hall, Royal ciety of Tropical Medicine and Hygiene, Manson House, 26 Portland ace, London, W.1), at 3 p.m.—Symposium on "Microbial Spoilage Industrial Materials".

Bone and Tooth Society (at the Institute of Orthopaedics, 234 eat Portland Street, London, W.1), at 5 p.m.—Symposium on one and the Kidney". Dr. W. Sheldon: "General Introduction on nal Function with regard to Bone Disease, including History of nal Dwarfism and Rickets"; Dr. F. Harwood Stevenson: "Clinical anifestations of Kidney-parathyroid-bone Relationship"; Prof. L. Baker: "Histology of Bone Disease with Impaired Renal nction", Dr. C. E. Dent: "Normal Renal Functions which could fect Bone Metabolism"; Dr. T. F. Dixon: "Biochemical Findings Bone Disease of Renal Origin".

Institute of Physics, Electronics Group (at 47, Belgrave Square, ndon, S.W.1), at 5.30 p.m.—Dr. F. Ashworth: "Field Emission enomena".

Institution of Electrical Engineers, Measurements Section Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. F. Coales: airman's Address.

Institute of Physics, Education Group (at the Royal Institution, bemarle Street, London, W.1), at 6.30 p.m.—Prof. O. R. Frisch, R.S.: "Atomic Energy—How it all Began".

Institute of Biology, London Branch (at the Society for iting Scientists, 5 Old Burlington Street, London, W.1), at 7.30 p.m. Dr. G. D. H. Bell: "Barley"; Mr. Frank Marshall: "Malt"; and . J. H. Oliver: "Brewing".

Royal Society of Medicine, Pathology Section (at 1 Wimpole reet, London, W.1), at 8 p.m.—Discussion on "The Applications Histochemical Methods to Pathology".

Wednesday, October 21

Geological Society of London (at Burlington House, Piccadilly, ndon, W.1), at 5 p.m.—Prof. J. Z. Young, F.R.S.: "The Evolution Vertebrate Organization" (William Smith Lecture).

Royal Meteorological Society (at 49 Cromwell Road, South nsington, London, S.W.7), at 5 p.m.—Scientific Papers.

Royal Society of Medicine, Comparative Medicine Section 1 Wimpole Street, London, W.1), at 5 p.m.—Mr. T. J. Bosworth: ontrol of Livestock Diseases in Britain: Some Reflections on the esent Situation" (Presidential Address).

Royal Microscopical Society (at Tavistock House South, Tavi- ok Square, London, W.C.1), at 5.30 p.m.—Mr. J. Smiles: "Pract- l Microscopy—The Development of the Stage-Picture".

British Psychological Society, Social Psychology Section the Psychology Department, University College, Gower Street, ndon, W.C.1), at 8.15 p.m.—Mr. T. H. Pear: "Social Differences English Sports and Games".

Thursday, October 22

University College, London (in the Anatomy Theatre, Gower reet, London, W.C.1), at 1.15 p.m.—Dr. Randolph Quirk: "Careless lk: Some Features of Everyday Speech".*

Linnean Society of London (at Burlington House, Piccadilly, ndon, W.1), at 5 p.m.—Dr. J. Heslop-Harrison: "The Genus *ctylorchis* in Britain: a Problem of Variation".

Institution of Electrical Engineers, Utilization Section (at voy Place, London, W.C.2), at 5.30 p.m.—Mr. B. L. Metcalf: airman's Address.

Thursday, October 22—Saturday, October 24

Institution of Metallurgists (at Grosvenor House, Park Lane, ndon, W.1).—Platinum Metals Exhibition.*

Thursday, October 22—Sunday, October 25

Council for the Preservation of Rural England (in con- ction with the Council for the Preservation of Rural Wales, Malvern)—"The Countryside—Profit and Loss" (Fourteenth tional Conference).

Friday, October 23

Textile Institute (at 10 Blackfriars Street, Manchester 3), at .m.—Prof. E. Honegger (Switzerland): "Some Aspects of Textile velopments as Seen from Switzerland" (Emsley Lecture).

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion. "The Determination of the Geoid". Chairman: Dr. G. M. Lees, F.R.S.; Speakers: Dr. J. de Graaff Hunter, Brigadier G. Bomford and Dr. A. H. Cook (for Prof. Heiskanen).

Physical Society (at the Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Prof. J. Bartels (Gottingen): "Chree's Influence on Present-day Geophysics".*

Society of Public Analysts and Other Analytical Chemists, Physical Methods Group (in the Lecture Hall, The University, Southampton), at 5 p.m.—Scientific Papers.

Institute of Physics, Industrial Radiology Group (at 47 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. R. H. Herz: "Theory and Practice of Auto-radiography".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (graduate in chemistry, biochemistry, physics or microbiology) for duties which will include the supervision of laboratory work—The Registrar, National College of Food Technology, Cranwood Street, City Road, London, E.C.1 (October 24).

Analytical Chemist (with at least B.Sc. degree, or equivalent qualification in chemistry) in the Health Department, Southern Rhodesia Government, to carry out the analysis of waters, food and drugs, dairy produce and certain chemical specimens; toxicology and forensic chemistry; general miscellaneous analyses—The Secretary, Southern Rhodesia Government, Rhodesia House, 429 Strand, London, W.C.2 (October 31).

Assistant (preferably with pass degree or equivalent in botany or zoology, and practical experience in collection and identification of invertebrates) in the Nature Conservancy Biological Research Station, Grange-over-Sands, Lancashire, for survey and experimental work on soil fauna in the field and laboratory—The Establishment Officer, The Nature Conservancy, 91 Victoria Street, London, S.W.1 (October 31).

Assistant Lecturer (preferably with special qualifications or interests in stratigraphy) in Geology—The Registrar, University College of North Staffordshire, Keele, Staffs (October 31).

Principal Scientific Officer (preferably with first- or second-class honours degree in chemistry, and good experience in modern metallurgical techniques) at the Ministry of Supply, Culcheth, Warrington, to take charge of staff providing analytical services to Metallurgical Research and Development Division—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.473/53A (October 31).

Scientific Officer or Senior Scientific Officer (with first- or second-class honours degree, and a good knowledge of physical chemistry), for (*a*) research on freshwater algae, (*b*) research into the physical and chemical conditions in the bottom deposits in fresh waters, and the exchange of substances between these deposits and the overlying water—The Director, Freshwater Biological Association, The Ferry House, Ambleside, Westmorland (October 31).

Lecturer (with degree or recognized diploma in mining) in the Department of Mining and Geology—The Principal, Wigan and District Mining and Technical College, Wigan (November 2).

Research Assistant (honours graduate in physics or mechanical engineering) to the Professor of Wool Textile Engineering, for fundamental studies of textile machinery and processes—The Registrar, The University, Leeds (November 2).

Lecturer (preferably with special interest in electronic and/or communication engineering) in Electrical Engineering—The Registrar, College of Technology, Manchester 1 (November 9).

Chair of Electrical Engineering, and Chair of Physics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (November 14).

Lecturer in Forestry (preferably with emphasis on either forest mensuration and management or forest exploitation, utilization and timber technology)—The Secretary and Registrar, University College of North Wales, Bangor (November 15).

Demonstrator in Agricultural Chemistry—The Registrar, The University, Leeds 2 (November 16).

Chair of Organic Chemistry—The Secretary, Queen's University, Belfast (December 3).

Assistant Physicist, basic grade (with honours degree in physics, and preferably with previous hospital experience) for duties in the Radiotherapy and X-Ray Diagnostic Departments—The Personnel Officer, St. Thomas's Hospital, London, S.E.1.

Assistant Lecturer in Chemistry—The Registrar, University College, Leicester.

Biochemist, basic grade (B.Sc. or equivalent, and preferably with experience in tissue metabolism studies) in the Research Department—The Director of Research, Barrow Hospital, Barrow Gurney, near Bristol.

Chief Instrument Engineer (with A.M.I.Mech.E., A.M.I.E.E., A.Inst.P., or equivalent) to take charge of an Instrument Design Team at Risley, and an Instrument Development Centre at Capenhurst—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, quoting 498

Entomologist (with university qualification with biology or entomology as a special subject, and preferably with some experience in taxonomy of Culicidae) in the Malaria Service of the Medical Department, Government of Nigeria—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.117/14/014.

Graduate (preferably with some knowledge of the steel industry) to undertake research on the flow of technical information in the steel industry—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "Information".

Joseph Hunter Chair of Pathology—The Registrar, The University, Sheffield.

LECTURER (with good honours degree in mining engineering, and wide knowledge of mining ventilation and fluid mechanics) IN MINING ENGINEERING—The Registrar, The University, Nottingham.

PHYSICISTS or MATHEMATICIANS, Senior Scientific Officers or Scientific Officers (with first- or second-class honours degree or equivalent in physics or mathematics), for (*a*) to lead small team engaged in analysis of photographic observations, and be responsible for both measurement and interpretation of records and to carry out research on methods of obtaining maximum information from existing photographic instruments; (*b*) to take charge of optical laboratory and to undertake optical design associated with high-speed photographic systems (Ref. A.258/53A). Assistant Experimental Officer (with at least H.S.C. (science) or equivalent) to measure and assess photographic records, and practical work connected with calibration of photographic instruments (Ref. A.259/53A), at the Ministry of Supply Atomic Weapons Research Establishment, Fort Halstead, Kent—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

PLANT PHYSIOLOGIST (with good honours degree and with post-graduate research experience) to direct and undertake fundamental biochemical investigations with a view to the ultimate development of mass culture techniques for the lesser known marine algae of potential industrial value—The Secretary, Institute of Seaweed Research, Inveresk, Midlothian.

SCIENTIFIC OFFICER (with honours degree or equivalent in mechanical engineering, and preferably with experience in agriculture) with the British Society for Research in Agricultural Engineering—The Scottish Machinery Testing Station, Howden, Mid Calder, Midlothian.

SOIL SCIENTIST (with good honours degree in geography with bias towards physical geography, and sufficient knowledge of chemistry to undertake a course in soil science) in the Department of Agriculture, Nigeria, for work on classification and mapping of soils—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.63/14/68.

BUILDING ACCOMMODATION FOR TECHNICAL EDUCATION

THE twelfth report from the Select Committee on Estimates for the Session 1952–53[*] records the results of the Committee's examination of the estimates for public education for 1953–54 so far as they relate to technical education. To the report are appended minutes of evidence taken from representatives of the Association of Principals of Technical Institutions, the Association of Technical Institutions, the Federation of British Industries, the Royal Technical College, Glasgow, and of other bodies, as well as of the Ministry of Education and of the Scottish Education Department. Annexes include memoranda on technical education in England and Wales, from the Ministry of Education and, on technical education in Scotland, from the Scottish Education Department. The scientist may also be interested in those on technical education from the Federation of British Industries, on the proposed college of technology at Sheffield and on the extension of the Manchester College of Technology. Taken together, the report and its appendixes give a comprehensive and authoritative, if scarcely concise, picture of technical education in Great Britain, which is relevant to some aspects of the discussion of the development of technological as well as of technical education, and some earlier comments on both are strongly endorsed.

The dominant impression derived from this report is almost exactly that to be derived from the Select Committee's eighth report, dealing with schools: the present rate in Britain of building for educational purposes is quite inadequate for the declared and agreed aims in education. Either those aims must be adjusted or more resources, taken from other activities, must be allocated to the task. That conclusion is not, indeed, specifically formulated by the Select Committee, though it is implicit in its general conclusion, and it stands out clearly in the Committee's comments on unsatisfactory buildings and on new building. Many of the buildings for technical education fall short of the requirements for good educational instruction. "In Birmingham the overcrowded condition of the College of Technology cannot be over-emphasized. Improvisation has been used to the limit. . . . Experimental work in the internal combustion engine department has sometimes had to be stopped in bad weather, owing to the need for covering the machines with tarpaulins to protect them from the rain." To continue the use of such buildings in their present condition much longer, the Committee justly observes, is not only to endanger life and limb but also to risk considerable danger of an eventual increased financial liability. Accommodation is also desperately needed in Sheffield, where the school of engineering is accommodated in converted disused schools and temporary buildings.

---

[*] Twelfth Report from the Select Committee on Estimates, together with Proceedings of the Committee of 29th July and the Minutes of Evidence taken before Sub-committee B on 10th June and subsequent days, and Appendices. Session 1952–53. Technical Education. Pp. xxii+173. (273.) (London: H.M. Stationery Office, 1953.) 7s. 6d. net.

It was admitted by the Ministry of Education in its evidence that almost all provision for construction is now being limited to fields—such as engineering, mining, textiles and buildings—serving industries supplying export and defence needs, and replacement of the many unsatisfactory technical school buildings does not appear to be envisaged. The Select Committee was satisfied that all those concerned, whether in central or local government or in independent establishments, are working in close harmony towards a single goal, and states emphatically that the enterprise being shown in improvisation and the determination to overcome all obstacles reflect the greatest credit on all concerned.

This unity and determination may well be due to the general unanimity as to the vital importance of technical and commercial education in the economic struggle with which Great Britain is faced to-day and which so impressed the Select Committee. It is undoubtedly recognized that Britain's competitive power in world markets and the higher productivity of her industries depend largely upon the degree to which technical and commercial knowledge and skill and wider educational opportunities are within the reach of all. This in turn depends largely upon the imagination, skill and ingenuity with which the programme of technical education is planned. Although the demand for all forms of technical education is still increasing, the Committee insists that persistence of the conditions referred to prevents a full return for the money spent on technical education, and that failure to provide satisfactory accommodation retards the national effort.

The present need is for proper facilities—in particular, adequate buildings where technical instruction can be given efficiently; until these exist in sufficient number, a full return will not be realized from public expenditure on technical education. In 1949 it was estimated that provision of minimum facilities for technical education in Great Britain would involve a post-war investment of about fifty million pounds. While this figure would now have to be increased by fifty per cent to allow for the rise in prices and other factors, only about ten per cent of the necessary work has been completed in the past five years. The programme is now running at the rate of four to five million pounds per annum; and this means that the complete programme will not be put in hand by 1959–60 as had been expected.

Nor is this all. The evidence submitted regarding the cost of certain technical colleges, only one of which (Norwich) has been completed since the War, shows that in present conditions continuous building is impossible. Each college is being built in instalments, a process admitted by all to be expensive in money, labour and materials. In spite of every effort by the local education authorities to mitigate the disadvantages of such a system of building by drawing up plans so as to minimize unnecessary work, evidence was submitted of sixty instances of piecemeal building of extensions. The Committee was unable to measure the full extent of the system or to assess the financial loss, not only in building costs but also in the hiring of temporary premises, often unsuitable, the duplication of expensive equipmen and the like; but it strongly recommends that th Ministry of Education should first re-examine th method of building in instalments with the view o eliminating to the maximum extent the financial los entailed, and secondly, consider the possibility o allocating money for building technical colleges t local authorities on a five-year basis.

Both industry and educational authorities favou the system of part-time day-release for technica education, and this also is the form most favoure by the trade union side of industry. A welcom feature of the report is the evidence that this deman for day-release training is increasing, and that it ca be met more easily than a demand for evening classes There is, however, also evidence that demands fo places in particular courses in technical colleges ar not being met. The Select Committee was unable t investigate the extent of this unsatisfied demand though it is confident that closer co-ordination a regional levels will help to solve the problem. I recommends that the Ministry of Education shoul ask the regional advisory councils, through th National Advisory Council, to ascertain the extent of the deficiencies, with the view of determining whether a larger portion of the money availabl should be used to meet this urgent need.

While in Scotland the practical importance of technical and technological education is becoming increasingly recognized, the Select Committee found that the difficult conditions in regard to buildings which it had noted in England prevailed in Scotland to a more serious and marked extent. This was evident at all levels, both in rural and industrial areas; and although some of the most urgent needs had been met, the quality of some of the provision left much to be desired. Nor could the financial cost or loss in technical efficiency caused by improvisations be measured. The Committee formed the opinion that, in Scotland, building for technical education purposes had been treated by local authorities as second in priority to building for primary and secondary school purposes, and it recommends that the Scottish Education Department should consider whether part of the grant which is made to some local education authorities for educational purposes should be earmarked for the building of new premises for technical education. It also recommends that the Scottish Education Department should consider, in the interests of efficiency, the establishment of a national advisory committee for co-ordinating the efforts of the five regional councils in the same way as is done in England and Wales.

The Select Committee points to the contrast between Scotland where, although the central government is willing to grant the money, the demand for building permission is not forthcoming from the local education authorities, and England and Wales, where local education authorities are pressing for a greater allotment of money and permission to spend, which the central government, because of present economic conditions, often withholds. This may not be entirely fair to Scotland, and has in fact been denied by some local authorities there. It overlooks the fact that, in being forced to choose between the construction of new schools for new estates and the expansion of technical education, local authorities, especially in Scotland, are forced to make policy decisions that should properly be made at the national level.

Nevertheless, the Select Committee has produced an extremely valuable survey of the present provision in the shape of buildings and accommodation for technical and technological education in Great Britain, and indicated some of its most urgent needs. The report will encourage those who have emphasized the urgency of this problem to redouble their efforts.

THE PSYCHIATRY OF TWINS

Psychotic and Neurotic Illness in Twins

By Eliot Slater, with the assistance of James Shields. Medical Research Council Special Report Series, No. 78.) Pp. vi+385. (London: H.M.S.O., 1953.) 21*s*.

THE mentality of twins gives ideal material for determining the separate influence of inheritance and environment. Even in their case, however, it is not perfect, since the very fact that two children are twins leads to their being given the same sort of background. It was Francis Galton who, in 1883, first directed serious attention to the personality of twins. This he investigated by personal inquiry, and the facts he ascertained from his friends and acquaintances were sufficient to show that uniovular twins not only resemble each other physically, but psychologically also. Moreover, he noticed that some twins resemble each other in developing similar types of insanity as well. Naturally, this attracted the attention of psychiatrists, but not until recently have other than anecdotal accounts of twins been published. During the past thirty years Siemens, Newman, Dahlberg, and others have discussed the various problems associated with them, although mainly without complete statistical analyses. In 930 Luxenburger laid down a more satisfactory basis for their study, and his work has been the foundation of it since. Gedda in 1951 published a very exhaustive examination of the whole matter, and now, finally, we have this excellent publication of E. Slater and . Shields.

The book is a long study. The first eighteen pages are concerned with previous work on unselected series of psychiatric twins; the next thirty pages describe the nature of the present investigation; and a further twenty-seven pages the clinical findings, five of which are devoted to the summary and conclusions, and twenty-one to genetical notes, age correction tables, finger-print formulæ and a statistical analysis of finger-prints. The rest of the book gives the complete case-histories.

The work was begun in 1936 on some twenty thousand mental patients and was later extended to a number of other mental hospitals as well as the Maudsley psychiatric clinic. The propositi numbered 95 born from multiple births. A great deal of interesting material was unearthed which can, perhaps, be given best by quoting from the authors' epitome. They state: "We found that 76% of the uniovular twins of schizophrenics had schizophrenic illnesses, a somewhat lower concordance rate than that of 86% found by Kallmann. Within concordant uniovular pairs there were often wide differences in the severity of the illness and in outcome. These facts suggest that the genetical causes provide a potentiality for schizophrenia, perhaps an essential one, though environmental factors play a substantial role, which may be decisive in the individual case. Those environmental factors which affect personality and constitution appear to be the most important. Heredity is also an important factor in the causation of affective and organic psychoses. There is a striking contrast between the psychoses on the one hand and the psychopathic and neurotic states on the other. In the latter, uniovular pairs were less frequently concordant, and some of the binovular pairs developed very similar troubles despite big differences in intelligence and personality. The dividing line between adjustment and maladjustment is not so wide as that between sanity and insanity and is more easily over-stepped, so that chance, whether favourable or unfavourable, is more important. However, personality is of even greater importance in these conditions than in the psychoses".

From this very honest and fair summary it can be seen that, although this work has been well worth doing and will, no doubt, be widely quoted extensively in the future, it does not solve the final problem of the nature of the psychoses, and only contributes towards that of the neuroses. Nevertheless it should be read by every psychiatrist interested in the origination of mental and nervous illness. The book is well printed on good paper but provided with an insubstantial cover which soon wore out in reading.

CLIFFORD ALLEN

AN INTRODUCTION TO EMBRYOLOGY

Entwicklungsphysiologie

Von L. v. Ubisch. Pp. 85+16 plates. (Berlin: F. W. Peters, 1952.) 9.50 D. marks.

THIS small book of less than a hundred pages is intended by Dr. L. von Ubisch, a well-known experimental embryologist living in Norway (in the language of which country it was first published), as a brief introduction to what may be called rather more correctly in German than in English, "developmental physiology". For it contains nothing about respiration, nutrition or excretion during embryonic development; it is concerned solely with the early phases of morphogenesis, and even so it has relatively little to say of the physiological mechanism of determination. The emphasis is on normal development, with enough experimental embryology to bring out the differences between eggs of mosaic and regulative type.

The treatment is systematic. First the normal development, as far as larval stages, is given for six forms (*Tubifex*, *Ascaris*, *Platycnemis*, *Paracentrotus*, an ascidian and an amphibian). These are illustrated with a sufficient number of clear drawings, which, however, would have been easier to use if the publisher had printed them on out-folding plates so that they could be studied while the text was read. There follows a systematic description of fragmentation and injury experiments in the different forms, in order to illustrate the varying degrees in which they are capable of regulative development.

Concluding chapters discuss determination itself, the problem of organizers and inductors, gradient theory, and the colloidal condition of the protoplasm of the cleavage cells, a question which particularly interests the author. He seems to show himself in these sections sometimes rather old-fashioned (for he still believes in "double assurance"), and sometimes bewildered (not inexcusably) by the wealth of information which has accumulated during the past twenty years on the physico-chemical nature of the inductor stimulus. It is one thing to maintain that in the past the intrinsic nature of competence (of a tissue to react), with all that that must imply for protein and surface chemistry, was not sufficiently taken into account; it is quite another thing to fall back, as Dr. von Ubisch does, and many other thinkers who are primarily zoologists do, upon "unspecific stimuli" as the normal mode of action of primary and secondary inductor phenomena. The author is again old-fashioned in his attachment to the gradient theory of Child, and seems unaffected by all the criticisms which physiologists have made of it; but he realizes that it has been absorbed in general field conceptions, which will probably always prove indispensable in this subject. Much more serious is the fact that there is no reference at all to important modern contributions such as those of Holtfreter, Toivonen, Brachet and Yamada.

Joseph Needham

PROGRESS IN LIPID CHEMISTRY

Progress in the Chemistry of Fats and other Lipids (Progress Series.) Vol. 1. Editors: Prof. R. T. Holman, W. O. Lundberg and T. Malkin. Pp. vii + 186. (London: Pergamon Press, Ltd., 1952.) 42s. net.

When Dr. H. Schoenfeld died, a new edition in English of the well-known Hefter–Schoenfeld "Chemie und Technologie der Fette und Fettprodukte" was in course of preparation, and it was decided that completed and projected manuscripts should be published as a progress series, of which this is the first volume. The technological contributions will form a companion series.

Since the space available for each contributor is obviously limited, the various chapters are likely to prove of more value to the non-specialist in their particular fields than to the man who is familiar with larger specialized publications. All the contributions are by experts in their field, and all are very readable.

T. Malkin deals with the molecular structure and polymorphism of fatty acids and their derivatives. The chapter is well illustrated with diagrams which, with the simple textual descriptions, make what might otherwise be a difficult subject delightfully lucid. After describing the structure of the unit cell, the discussion of polymorphism follows logically. Thus, the higher melting point of methyl than of ethyl esters is in line with crystallographic evidence of association due to the methyl groups. Alternation of certain properties peculiar to the solid state (for example, melting point) between odd and even members in some series of long-chain compounds (for example, fatty acids and methyl esters) but not in other series (for example, hydrocarbons, alcohols and ethyl esters) is convincingly explained as due to the non-alternating substances possessing long chains vertical to the end faces and the alternating series possessing tilted chains.

The chapter on sterols by W. Bergmann suffers from over-condensation in some sections since, although it is the longest in the book, more than fifty sterols are discussed, requiring about half the total space to list their formulæ and properties. This section is admirable, as is the author's classification scheme based on the optical rotation of the sterols and their derivatives. Excessive condensation occurs particularly in the sections dealing with analytical and preparative methods, which could, of course, easily be the subject of a whole chapter. Thus, the flat statement that "the most effective [micro] method [for the determination of sterols] appears to be the one developed by Schoenheimer & Sperry" does less than justice to a tremendous volume of literature, particularly since the one reference quoted is dated 1934, the later studies of Sperry himself also being ignored. There are other cases where later literature references might have been made—for example, in connexion with the biosynthesis of cholesterol, where by 1950 Little and Bloch had identified the origin of carbon atoms 10, 18, 19, 25, 26 and 27.

The section on the structure and properties of phosphatides, by P. Desnuelle, gives a curious impression of lecture style rather than prose style, probably because English is not the author's native language. Doubtless for the same reason, the argument at times is not readily followed. Thus, on p. 73 coconut and palm kernel are not mentioned in the table indicated by the text. The statement (p. 74) that all phosphatides involve an ester link between fatty acid and alcohol is incorrect (sphingomyelin) while Hilditch most certainly has *not* suggested random distribution of fatty acids in animal fats (p. 79). A serious error is the quoting of Klenk and Debuch (p. 80) as evidence of the occurrence o polyethylenic C_{20} and C_{22} acids in vegetable phosphatides—the title of Klenk and Debuch's paper is presumably responsible. This chapter suffers seriously throughout from inadequacy of discussion and literature references, and the subject is obviously too extensive for the space available.

R. T. Holman has provided, as one might expect a most instructive account of the chromatography o fatty acids and related substances, including elution analysis, frontal analysis, displacement analysis and partition chromatography. The list might with advantage have been extended to include countercurrent distribution, which is so closely related t partition chromatography. The author emphasize the empirical nature of most chromatographic techniques and points out the confusion which ha resulted, since few experiments are comparable. H comments that chromatography has not yet reached the stage of a routine tool in the examination o lipids. Despite all these provisos, chromatographic techniques have effected some gratifying separation of lipids otherwise difficult to handle, and on micro-scale.

H. J. Harwood has contributed a very detaile account of certain fatty-acid derivatives in which the carboxyl group is involved; but the sketchy section on derivatives involving the hydrocarbon chain migh preferably have been omitted or incorporated, wit more detail, into another (promised) chapter in later volume. The main section of the chapter well illustrated with equations, tables and figures and industrial uses of many of the derivatives ar listed, nitrogen derivatives occupying the greate part of the account.

J. A. Lovern

Dimensional Analysis

By Prof. H. E. Huntley. Pp. 158. (London: Macdonald and Co. (Publishers), Ltd., 1952.) 20*s.* net.

PROF. H. E. HUNTLEY has re-drafted the material of a lecture course for university physics students into book form to meet the obvious need for a text-book devoted entirely to the subject of dimensional analysis. The first part of the book is devoted to a discussion of the method in its simplest form with a number of worked examples. The second part attacks the problem of extending the number of fundamental quantities in order to remove some anomalies. For example, the dimensional formulæ for torque and work (both L^2MT^{-2} on the usual system) acquire a significant difference when the single dimension of length is replaced by three components along mutually perpendicular directions; torque becomes $L_XL_YMT^{-2}$ and work becomes $(L_X)^2MT^{-2}$. Similarly, certain advantages follow a distinction between mass as a quantity of matter and inertial mass—particularly in thermal problems. The consequences of these changes are discussed, and numerous examples of the use of the modified systems are given.

Unfortunately, the discussions are not as critical as could be desired, and the arguments and illustrations are not always entirely convincing. There are also one or two rather curious statements. For example, on p. 48 we read that the method of dimensions makes use of the principle ". . . that each term of a proper physics equation must be of the same dimensions in the fundamental quantities as every other term". One wonders what form of impropriety distinguishes those equations which obey the principle from those which do not.

However, although one would hesitate to recommend it to any but the most critical students, the defects seem to be rather in presentation than in basic material and, to the more mature physicist, it should present some stimulating ideas. It should certainly be read by all teachers of the subject.

C. A. TAYLOR

Algebraic Projective Geometry

By Prof. J. G. Semple and G. T. Kneebone. Pp. vii+404. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 35*s.* net.

THIS book provides honours students of mathematics with a rigorous axiomatic account of projective geometry, on an algebraic basis, assuming a knowledge of matrices and of such algebraic concepts as field, ring and group. The first chapter gives a brief account of the evolution of geometry from earth-measuring to a purely abstract system. The second chapter gives an elementary analytical treatment of projective geometry, linking it up with the usual co-ordinate geometry. These two chapters are merely introductory; the real subject of the book, the abstract axiomatic treatment, starts in Chapter 3, and is logically independent of all previous geometrical knowledge. Chapters 3–9 deal in this way with homography, conics, higher correspondences, apolarity, invariants, collineations and other transformations, with emphasis on Euclidean and affine specializations of projective geometry. In dealing with one and two dimensions it is found "necessary to proceed slowly and cautiously by small algebraic steps"; but when three dimensions are reached it is possible to "begin to detach ourselves from the details of algebra, making use once more of geometrical intuition, but this time less naïvely" (than in Chapter 2). The last seven chapters, perhaps the most interesting, deal not only with quadrics but also with some of the properties of the twisted cubic, cubic surfaces, line geometry and space of four and more dimensions. The book concludes with two basic algebraic theorems (one not proved here, as its proof is well known) and an index. There are numerous exercises in the text and at the end of every chapter except the first.

H. T. H. PIAGGIO

Mr. Tompkins Learns the Facts of Life

By Prof. George Gamow. Pp. xi+88+6 plates. (Cambridge: At the University Press, 1953.) 12*s.* 6*d.* net.

IN his elementary discussions on relativity, topology, philosophy and logic the late Rev. C. L. Dodgson takes the immortal Alice through a series of adventures which are so richly veiled in fantasy and humour that the meaning of the parable is not always apparent. Prof. George Gamow's wonderland is that of vitamins, chromosomes, cybernetics and energy changes in the life-cycle. His Alice is Cyril George Henry Tompkins, an American bank clerk "who was born at a comparatively late age, apparently in 1939". Very properly for Mr. Tompkins and his creator "the facts of life" have a broader and truer meaning than is usually given to them in Britain.

The present book is the last of a trilogy, the author having dealt in a similar manner with relativity and atomic physics. He is no less successful with his excursions into human biology. In a series of dream adventures, with the help of a variety of guides (including a masterly gene and a talkative electronic brain called the "Maniac"), Mr. Tompkins learns what answers genetics and biology can give to some of the questions about the nature of life. The author does not shrink from the difficulties of: What is life? How did it start? How do certain forms of atoms combined into complex molecules become living cells? He explains how a fundamental characteristic of life is negative entropy. He sums up, in terms that any ordinary thinking person can grasp, the present state of biological knowledge and the answers that it can give to some of the questions about ourselves and about life that have always bothered our minds.

W. L. SUMNER

Colloid Science

Edited by H. R. Kruyt. Vol. 1: Irreversible Systems. Pp. xx+389. (New York and Amsterdam: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1952.) 70*s.*

THIS book offers an expert account, although not a completely comprehensive one, of the properties of lyophobic colloids. The presentation is not elementary, and mathematics is not avoided, the text inclining generally to a theoretical rather than a practical emphasis. Apart from an introductory chapter by Prof. H. R. Kruyt and a contribution on the optical properties of colloidal solutions by Dr. G. H. Jonker, the book is entirely written by Prof. J. Th. G. Overbeek, of Utrecht. He gives a detailed treatment of the electrochemistry of the double layer and of electrokinetic phenomena and also discusses interaction between colloidal particles and the kinetics of flocculation. Questions of stability are dealt with, and there is a brief account of the rheology of lyophobic systems. This contribution from the Dutch school to the growing literature of colloid science will be welcomed by research workers and advanced students who are not afraid of making an effort as they read.

D. P. RILEY

FIFTY YEARS OF POWERED FLIGHT*

By Sir BEN LOCKSPEISER, K.C.B., F.R.S.

TO fly like the birds was for centuries man's dream and desire. The Wright brothers succeeded where so many others had failed because of the relentless scientific attack they made on the problem of flight. "The world is not fully aware of all the tedious, gruelling scientific laboratory work they had to do before flight was possible." They invented the wind tunnel to study and measure air forces, invented their own system of control and overcame difficulties of stability. They designed and built their own engine of some 20 horse-power, weighing not more than 240 lb.—itself a triumph of engineering at the time—and in the end designed and made a machine that would lift itself. Exactly fifty years ago this year, they flew this machine at Kitty Hawk in the United States and fulfilled the dream that man had cherished throughout the ages. It was a great achievement based on a rare combination of science, invention and engineering, and was one of the epoch-making events in history.

It is doubtful whether this machine ever climbed more than 10 ft. above the ground, for it had too much drag, too much weight and too little power to leave much margin for climb. But it was enough. A revolution in transport had been started. The main principles having been established and successfully demonstrated, progress was rapid. Six years after the flight of the Wright brothers, Blériot crossed the English Channel in forty minutes, and within sixteen years Alcock and Brown flew the Atlantic, for the first time, in less than seventeen hours. These three machines have changed the course of history.

Significance of Streamlined Design

Low drag involves something more than absence of unnecessary parts projecting in the air stream. It implies certain standards of excellence in shape and lines; streamlined, in fact, and the lines we speak of are lines of air flow which, could they be made visible, as they can be experimentally by means of smoke, would be seen, in a perfect shape, to bend smoothly and flow snugly around curved surfaces of the structure, leaving no turbulent wake. Any departure from the ideal aerodynamic shape promotes the breakaway of the air flow from the surface and the formation of large-scale eddies or turbulence. This churning up of the air is sheer waste, and the power to produce it makes an unnecessary call on the engine. A very large effort has been spent in learning how to avoid this and to design and produce low-drag wings. By careful design and construction and smoothness of surface we can achieve laminar flow over more than half the depth of the wing (or chord as it is called), when a transition occurs from the laminar to a turbulent type of flow which gives rise to an increase of drag. The best aircraft flying to-day carry wings capable of producing this type of flow, and we may be able, in the future, by the use of slots in the wing or porous wing surfaces, to control the air flow by suction and push the transition point farther back to produce a near approximation to laminar flow.

For bodies moving in air at speeds below and not comparable to the speed of sound, the air behaves for all practical purposes as though it were incompressible, that is, its compressibility can be ignored. This does not hold as the speed of sound is approached. The velocity of sound in air at sea-level is about 760 m.p.h. and the effect of the compressibility begins to make itself sensibly felt above about 500 m.p.h. The effect of compressibility is to produce an increased drag rapidly growing with rising speed and reaching at the speed of sound a value many times greater than would be encountered if the air remained sensibly incompressible.

It is not immediately obvious why the speed of sound should play such a dominating and decisive part, and perhaps a few words from a purely physical aspect will not be out of place. At a speed well below the speed of sound or, as it is called, a low subsonic speed, the air conforms to a smooth flow pattern which extends forward of an aerofoil. The air ahead of the aerofoil is prepared in advance for its arrival, part being accelerated to flow over the upper surface and part over the lower surface. Clearly, the moving aerofoil possesses as it were a signalling system to warn the air ahead of its approach and allow it to take full advantage of its shape to slip through. What I have called the signalling system is based on changes of air pressure. The flow pattern is also a pressure pattern, for wherever the flow lines are curved a change of pressure occurs, giving rise to the lift and drag of the aerofoil. It is clear from the flow pattern that there is a pressure change ahead of the aerofoil, and this is the physical basis of the signal. Pressure changes in any medium are, however, not transmitted instantaneously, but with a particular velocity, dependent on the medium, and this velocity for pressure changes of the order of magnitude under consideration is the speed of sound in air. It follows, therefore, that if the aerofoil is travelling at or above the speed of sound (that is, at sonic or supersonic velocity) it is robbed of any means of signalling ahead. The air can no longer be prepared for its arrival. The aerofoil can no longer slip smoothly through the air: it now meets it, inevitably, head on, producing a shock wave which is the source of the largely increased drag.

This is fundamental, for it is impossible to avoid the formation of shock waves whenever the velocity of the air relative to the surface exceeds the local speed of sound. This is bound to happen at a forward speed appreciably below the speed of sound in the atmosphere, because the air is accelerated in its flow over a curved body such as a wing. The shock wave occurs at the downstream end of the local region of supersonic flow, and behind it the speed is subsonic. The position of the shock wave depends on the shape of the wing section and its incidence, as well as on the forward speed. [A film, taken in a wind tunnel at the National Physical Laboratory, illustrated the formation of shock waves on a conventional symmetrical aerofoil as the speed increased from subsonic to supersonic, and showed the movement of the first shock wave back towards the trailing edge as the speed increases at constant incidence.] When the shock wave moves back, the low pressure in the region of supersonic flow ahead of it extends over a larger fraction of the aerofoil surface, and there is therefore a movement of the centre of pressure with speed and incidence. This causes a considerable change in the stability of the aircraft. The occurrence of shock waves may also cause conventional control surfaces to become relatively ineffective, and this has led to the adoption of all-moving tail planes as in the North American "Sabre". At supersonic forward speeds a bow wave is formed, and the flow again becomes stable with no serious changes in the position of the centre of pressure as the speed or incidence is varied.

---

* Substance of an Evening Discourse at the Liverpool meeting of the British Association, delivered on Sept. 4.

Matters are complicated by the fact that the speed of sound does not remain constant but, because of the fall in temperature, decreases with altitude. It falls continuously from 760 m.p.h. at sea-level until the stratosphere is reached, where the speed is 660 m.p.h. An aircraft flying at, say, 600 m.p.h. in the stratosphere is much closer to the speed of sound than when flying at this speed at sea-level. The significant and determining factor in compressibility phenomena is thus not the actual speed of the aircraft itself but the ratio of its speed to the velocity of sound at the altitude at which the aircraft is flying. It is usual, therefore, in dealing with the performance of high-speed aircraft to speak of the Mach number, that is, the ratio of the forward velocity to the local velocity of sound.

It is clear that the onset of shock wave conditions at high subsonic speeds can be delayed by reducing the acceleration produced by curvature, and high-speed flight therefore calls for slim wings, nacelles and bodies. These increase the speed at which shock waves first appear, called the critical speed, which can be raised still further by the use of swept-back wings, the effect of which is to reduce the effective thickness-to-chord ratio of the wing in the direction of flight, and hence to reduce the curvature of the wing surface. The effect of sweep-back in delaying the rise of drag is illustrated in Fig. 1, which compares the drag curves of two hypothetical modern aeroplanes of equal wing-areas—one square-winged and the other swept back 45°. The diagram illustrates also that the advantage of sweep-back disappears at high Mach numbers. A typical modern fighter having swept-back wing and tail surfaces is the Hawker "Hunter".

High sweep-back, however, creates difficulties of its own. The twisting of the wing under load causes loss of lift at the wing tips, which in the swept-back wing are well behind the centre of gravity of the aircraft, giving rise to problems in pitch control. The degree of sweep-back required is related to the curvature of the wing surface which, diminishing progressively from the wing root to the tip, leads ideally to a crescent shape for a swept-back wing, thereby easing the control problem. This principle is embodied in the Handley Page "Victor" jet bomber.

The swept-back wing has been taken a step further in the so-called "Delta" wing aircraft, which embodies a swept-back leading edge and an unswept trailing edge, with the chord falling uniformly until it is zero at the tips. The main advantages of the "Delta" wing are its increased stiffness and stowage capacity: the former diminishes the wing tip problem already referred to and helps to avoid flutter. The large centre-section thickness which becomes possible with a long centre-section chord enables jet engines to be completely buried in the wing, and space is also available for more fuel and payload. The latest "Delta" wing aircraft flying is the Avro "Vulcan" jet bomber.

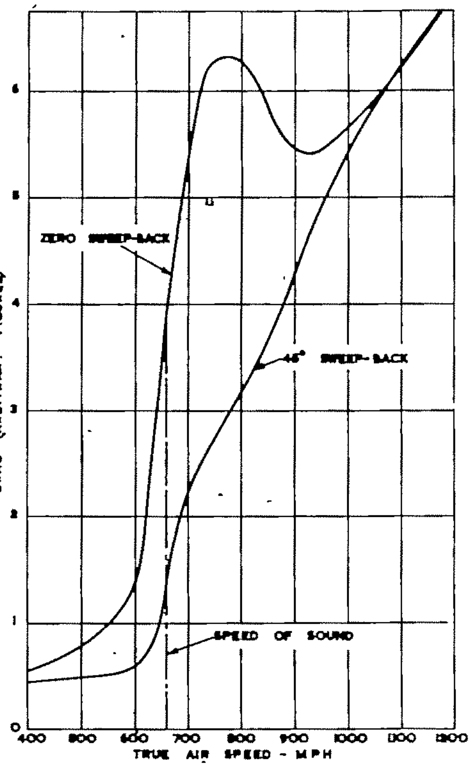

Fig. 1. Effect of sweep-back on drag at 40,000 ft. (equal wing areas)

Propeller versus Jet for Motive Power

We have, therefore, means at our disposal for reducing the drag of aircraft both up to and well beyond the speed of sound; but the drag at these high speeds is, however, formidable enough, and the thrust to overcome it has only become possible by the introduction of the gas turbine and propulsion by reaction from a very high-speed jet of gas. Propellers, like aircraft wings, are subject to compressibility drag effects, and the combination of forward and rotational velocities introduces increasing drag conditions over a considerable portion of the blade area after about 400 m.p.h. Up to this point, from comparatively low speeds, the propeller is a very efficient means of propulsion, efficiencies of about 85 per cent being not uncommon; but at higher speeds compressibility drag becomes of increasing significance and the efficiency drops sharply. This is shown in Fig. 2, which contrasts this behaviour with the rise of efficiency of the jet as a means of propulsion, and explains why the use of a jet is so necessary for high-speed propulsion.

On this showing, the propeller ought to hold its own with the jet up to speeds of at least 500 m.p.h. and, theoretically, even beyond this figure, by the application to propellers of the principles of wing design for reducing compressibility effects already referred to. But, in practice, propulsion by jet is ahead of the propeller at lower speeds than this, because of other considerations. The elimination of the propeller eliminates also the disturbance of the air flow over the wing besides saving the weight and drag of the propeller. The turbo-jet engine is much

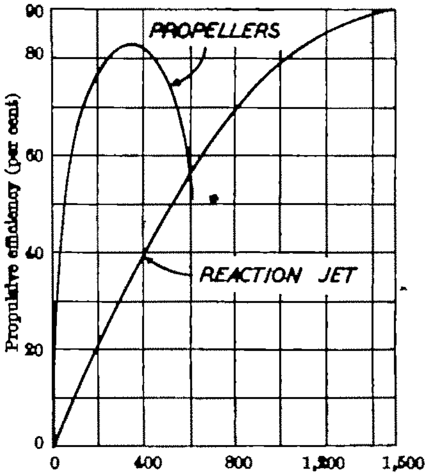

Fig. 1. Comparative propulsive efficiencies

lighter and occupies less space than a corresponding piston engine, offset though this is by the jet engine's higher fuel consumption. Range, of course, plays a determining part in the balance of these factors, but it is not the only one. The turbo-jet, particularly with axial flow compressor, can be built with a much smaller frontal area per unit of thrust than any other type of air-consuming engine, and it can be made to develop thrusts far in excess of anything hitherto obtainable. The superior efficiency of the jet over the propeller as a means of propulsion at high speeds, the absence of any propeller slipstream to increase drag, the comparatively small engine frontal area and the very high thrusts obtainable from these jets are the main reasons why the turbo-jet has swept the field in the high-speed range. Nor should we overlook the fact that the gas turbine is not fussy about the nature of its fuel. Aero piston engines demand expensively manufactured fuels of high octane number, whereas the aero gas turbine will burn either cheap motor spirit or paraffin. Paraffin is preferred because it gives less trouble with vapour-locking at altitude, and because its calorific value per unit volume is slightly higher.

Before the introduction of the gas turbine, the piston engine had already been developed to a high degree of excellence both in performance and reliability. Concurrently, its weight per horse-power had been reduced from the Wright brothers' 12 lb. per b.h.p. to just over 1 lb. per b.h.p. to-day; and in co-operation with the fuel technologists its specific fuel consumption (that is, the fuel consumed per b.h.p. hour) has been brought down from about 0·6 to 0·42 lb./b.h.p./hour. The aircraft diesel engine was not put into production in Britain, but in Germany the ingenious Junkers Jumo 205 opposed-piston two-stroke diesel engine had given consumption figures as low as 0·36 lb./b.h.p./hour in service. Unfortunately, it was very heavy for its power, weighing 1·8 lb. per b.h.p.

As I have already indicated, the gas turbine introduced by Whittle has revolutionized aircraft propulsion by making possible speeds which would be unattainable with a piston engine and propeller. The gas turbine can be used in two ways. First, all the power developed by the turbine is used to drive the compressor, and the exhaust is discharged as a high-speed, high-temperature jet of gas; this is the turbo-jet, of which the Rolls Royce "Avon" is a typical example. Alternatively, part of the powe developed by a more powerful turbine—commonl about one-third—can be used to drive a propeller this is the turbo-propeller engine. Each type o engine has its place in the field of aircraft propulsio

The propeller turbine, intermediate between th straight jet and the piston engine and propeller, i heavier than the straight jet, but makes much mor economical use of the same kind of cheap fuel. I can be quieter than any other kind of aircraft engin yet produced, and it is almost vibrationless. Th Armstrong Siddeley "Mamba", is an example of thi type of engine.

Fuel Consumption

Although we hear much about supersonic flight which, of course, has been achieved, it is being mor and more realized, if only because of the very hig fuel consumption demanded by such high speed that it will be a very big step from our present sub sonic civil airliners to the supersonic versions. Whe operating at extreme range, the "Comet I" takes o with 22 tons of fuel for 21 tons of aeroplane and fou tons of crew and payload. Increasing attention i therefore being paid to the problem of greatl improving overall propulsive efficiency at hig subsonic speeds. This can be done by the ducte fan or by-pass engine, which increases the mass flo of air through the engine and reduces the mean je velocity. Such engines will probably reduce the fue consumption by 25 per cent as compared with straight jet. The Rolls Royce "Conway" is an engin of this type. It is a likely power plant for the D Havilland "Comet's" successor.

The present emphasis on jets does not mean tha the piston engine can be entirely forgotten. In smal sizes, the gas turbine cannot compete with it in fir cost or economy of operation. In large sizes, provide one does not want to fly much faster than 300 m.p.h. the compound engine (part piston, part turbine) ca beat all the others for very long-range operation. I the United States, compound engines have bee produced by addition of multiple-exhaust turbine geared to the engine crankshaft. The Wright "Turbo-Cyclone" is an example of this: it has a cruisin specific fuel consumption of 0·39 lb./hr./b.h.p. an has been chosen to power the latest American long range civil aircraft, such as the "Super-Constellation" In Great Britain the compound engine has, in m opinion, been tackled more fundamentally, and w now have the Napier "Nomad", which uses a two-stroke diesel engine with a high-pressure exhau turbine. This engine has achieved the lowest specifi fuel consumption ever recorded for an aircraft engin (0·33 lb./hr./b.h.p.) and weighs only 1·2 lb. per b.h.p

Modern Alloys in Aircraft Design

The metallurgist has played a leading part in th great advances made in both aircraft and engine When the Wright brothers flew, aluminium was littl more than a scientific curiosity, a low-density wea metal of about 5 tons per sq. in. tensile strength Modern aircraft aluminium alloys have a tensil strength as high as 40 tons per sq. in. with a densit one-third that of steel, and the proof stresses o aluminium alloys have been almost doubled sinc the time of the First World War—an outstandin achievement providing a striking example of progre made under the spur of necessity.

The development of light alloys which could b rolled into sheet of high strength coincided wit important advances in structural science and led to the introduction of the cantilever monoplane, which created a major revolution in aircraft engineering. The main structural change was the introduction of stressed skin or monocoque construction. This innovation killed two birds with one stone. It replaced fabric with a more robust material, more capable of resisting deformation and change of aerodynamic shape, and it enabled the surface covering to contribute very substantially to the strength of the structure as a whole. It made the most efficient use of material by placing it as near as possible to the outside surface. The skin now provides nearly all the torsional stiffness, and it also contributes to the bending strength of the wing, thus enabling a reduction in the weight of the main spars to be made. The tail surfaces have developed on similar lines, while the fuselage early lent itself to monocoque construction.

The recently developed magnesium alloys, especially those containing zinc and zirconium, have proved of great value in light-weight castings, such as those for the reduction gear casings of aircraft gas turbines, for they have a strength/weight ratio nearly 20 per cent greater than that of the best aluminium alloys. Magnesium alloys are also becoming available as forgings, extrusions and rolled sheet with very promising engineering properties. High specific strength is not their only virtue: they can be machined faster and more easily than any other engineering material, and they have completely displaced aluminium alloys in aircraft wheels. Magnesium alloys now account for about one-third of all light-alloy castings supplied to the aircraft and engine industries, and the proportion is growing.

Light alloys based on aluminium and magnesium suffer, however, a rapid loss of strength with rise of temperature. This has for long been a serious drawback in piston engines, where the piston temperature has limited cylinder diameter and power output. In the gas turbine, compression raises the temperature of air leaving a compressor with a compression ratio of 6 : 1 to well over 200° C., and copper-bearing aluminium alloy blades are now giving way to those of titanium alloys containing chromium and iron, the strength characteristics of which with temperature, compared with those of aluminium alloys and sintered aluminium powder, are shown in Fig. 3. Titanium alloys which have so far been investigated are twice as strong as aluminium alloys for one and a half times the weight, and further improvements in strength/weight ratio may be achieved.

Alloys for aircraft, however, require to be not only strong for their weight but stiff also, and, in this respect, present-day titanium alloys are, on a comparative basis, inferior to both aluminium alloys and steel by about 10 per cent. This matters a great deal; for the development of the modern aeroplane, particularly as regards speed, has introduced a new criterion in design, namely, structural stiffness, which is now a consideration comparable in importance with strength. A reasonable degree of stiffness is essential on practical engineering grounds, but the main concern is with flutter. This is a complicated aeroelastic phenomenon in which, at a particular speed, dependent on the characteristics of the structure, oscillations occur of progressively increasing amplitude, rapidly ending in structural disintegration. Flutter is the skeleton in the cupboard of all high-speed aircraft designers, for all structures are liable to flutter in a wind in certain circumstances, and the higher the speed the greater the risk. The best a designer can do is to ensure, so far as he can, that the flutter speed is well above the highest practical flying speed. Various measures can be taken to this end, but high stiffness both in bending and twisting is the principal safeguard.

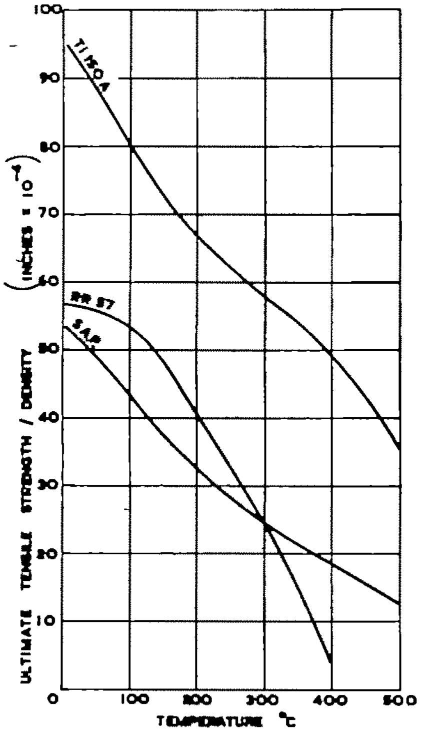

Fig. 3. Variations of ultimate tensile strength with temperature for various materials for compressor blades

In addition to strength and stiffness at the minimum cost in weight, a third criterion—fatigue—has to be taken seriously into account by the designer in his choice of materials, and this is becoming more and more a matter for anxiety as new alloys of higher static tensile strength come into use. Aircraft have to be designed to deal with not only their normal static loadings but also additional repeated loadings, due mainly to gusts encountered in the atmosphere, which vary greatly according to time and intensity. In the structural laboratory, complete wings are subjected to fluctuating loads broadly representative of a flight in bumpy weather until failure occurs.

Problems of Take-off and Landing

As a consequence of these advances in the several fields of science, technology and design, and with a recognition of the vital part played by the skill of pilots, aircraft speeds have increased steadily with the years, and at an increasing rate, from a maximum speed of 70 m.p.h. in 1910 to more than 700 m.p.h. in 1953. Fighter aircraft are, of course, built primarily for speed, but transport aircraft and civil airliners have to compromise on speed to fulfil the requirements of range and economy. Their maximum speed is therefore lower and their cruising speed, at which fuel is used more economically, lower still. Nevertheless, it is of interest to note that the cruising speed of jet civil aircraft is much closer to their maximum speed than is the case with propeller-driven aircraft.

High speed, however, carries certain consequences, among which is a high rate of fuel consumption which cuts into payload. We can get anywhere in the habitable world in hops of about 2,000 miles or so, and, as we pay for speed by fuel consumption, a fast aircraft at the beginning of a 2,000-mile flight is virtually a flying tanker. About half its all-up-weight is accounted for by fuel. This is not the only price we pay for speed, for higher flying speeds have involved higher landing and take-off speeds, and fast long-range aircraft are not only inevitably heavy but also demand long and expensive runways. Aircraft *weight* determines the thickness of concrete for a given sub-grade, and take-off speed, for a given acceleration, the length of runway. At the London Airport the longest runway is rather less than two miles, and concrete a foot thick is used on a stable gravel base. The airport covers nearly 3,000 acres and its estimated cost on completion is of the order of £21 million. If aircraft are to become larger and heavier, as is likely, the provision of concrete runways presents very serious economic problems.

The flying boat offers a possible means of escape. Until comparatively recently, the performance of the flying boat was inferior to that of the corresponding land plane, but several advances have now made it a serious competitor. The flying boat always had the advantage of being able to dispense with an undercarriage, which, in a modern large aeroplane, may account for 6 per cent of the total structure weight; but this was for a long time more than offset by the excessive size and weight of a hull which had to carry the propellers high above the water to keep them clear of the spray. Jet propulsion has changed all this, and a smaller hull, combined with improvements which can now be made in its aerodynamic design, may well tip the balance in favour of a flying boat for all-up weights of 50 tons and above.

Finally, we have in recent years come back to where Leonardo da Vinci began, and devoted serious attention to the rotary wing aircraft. It can never match the fixed-wing aeroplane for speed, but it can land on and take off from a small space, rise and descend vertically, and fly horizontally at a speed which gives it an advantage in door-to-door times for journeys of a few hundred miles.

THE MELTING OF IRON AT HIGH PRESSURES

By PROF. F. E. SIMON, C.B.E., F.R.S.
Clarendon Laboratory, University of Oxford

THE knowledge of the dependence of the melting pressure of iron on temperature would be of importance to geophysics. So far, however, no information about the melting of iron at high pressures exists and there does not seem to be much chance, in the foreseeable future, of obtaining it directly under conditions approaching those in the interior of the earth. Therefore, when I derived about twenty-five years ago a semi-empirical formula[1] connecting the melting parameters with the internal pressure, I applied it tentatively to the case of iron. At that time, however, the range of validity of the formula had not been widely explored and I therefore restricted myself to a few qualitative remarks[2].

In the meantime, the formula:

$$p/\alpha = (T/T_0)^c - 1, \qquad (1)$$

where α is a constant related to the internal pressure, T_0 is the normal melting temperature and c is a numerical constant, has successfully served as a guide to our experiments which have been pushed, in the case of the low melting point substances, to very high *relative* temperatures[3]; helium, for example, has been solidified at temperatures more than ten times the critical temperature. Also, the formula has recently been given a theoretical foundation[4] which, although not accounting for all the details, confirms the general form and the fact that it is the internal pressure of the condensed phase which is the determining quantity. Furthermore, recent experiments have at last provided reliable data for the heat of fusion and the volume change of iron at the normal melting point, whereas not long ago even the sign of the volume change was in doubt. These values make it possible to derive the initial slope of the melting curve and in this way to eliminate one of our constants. The time, therefore, seems appropriate to try to predict the melting pressures of iron at high temperatures, particularly in view of the increased interest of geophysicists, some of whom now assume that the core of the earth consists of solid iron surrounded by the liquid phase (see, for example, Bullen[5], Birch[6]).

The majority of substances for which the melting curves have been investigated experimentally—mainly by Bridgman[7]—are those held together by van der Waals' forces. For all these substances the constant c turned out to be nearly the same and of the order of 1·5–2. Our knowledge of the melting curves of metals is unfortunately much more restricted, practically to that of the alkalis, and here c was found to be much higher, as will presently be discussed.

Again, for the van der Waals substances the value of α was found[8] to be very nearly equal to λ_l/V (where λ_l is the energy difference between gas and liquid, and V is the volume of liquid), a value which can be derived by applying the thermodynamic expression for the internal pressure $\left(\frac{\partial U}{\partial V}\right)_T$ to the van der Waals equation. In the case of the metals, the agreement was poor, as could only be expected owing to the completely different type of binding forces; consequently we cannot calculate α for iron in this way.

In choosing our values of α and c, we can make use of the fact that the initial slope of the curve[2] is given according to (1) by:

$$\frac{dp}{dT} = \frac{c \cdot \alpha}{T_0}.$$

On the other hand:

$$\frac{dp}{dT} = \frac{r}{T\,\Delta V} \quad (r = \text{heat of fusion}),$$

and thus $c \cdot \alpha = r/\Delta V$.

Recently, Awbery[9] in a careful survey has come to the conclusion that the heat of fusion is 64–65 cal./gm., and I am grateful to Dr. R. W. Powell for informing me that recent unpublished experiments at the National Physical Laboratory confirm this value. Also new experiments of Stott and Rendall[10], again at the National Physical Laboratory, have shown that the volume of iron increases on melting by 3 ± 0·5 per cent. From these values we can derive

$$\frac{dp}{dT}_{(T=T_0)} = 330 \text{ atm./degree}$$

or,

$$c \times \alpha = 600{,}000 \text{ atm.} \qquad (2)$$

In trying to select the best values of c and α we have given in the first two columns of Table 1 the values which follow from Bridgman's[7] data for the melting curves of the alkali metals. Lithium has been omitted, as only values for a rather impure sample are available[11].

Table 1

	c	α (atm.)	$(\partial U/\partial V)_T$ atm.	$\alpha\Big/\left(\frac{\partial U}{\partial V}\right)_T$
Na	3·8	11,000	5,750	1·9
K	4·6	4,000	2,850	1·4
R	4·2	3,400	2,400	1·4
Cs	4·8	2,400	1,600	1·5
Average	4·5			1·5$_2$

One way to proceed would be simply to attribute a similar value of c to iron, namely, 4·5, which in turn would imply α = 133,300 atm. On the other hand, too little is yet known on how c depends on the constitution of the substance, and it is desirable to have an independent way of calculating one of the constants. In the third column of Table 1 we have given the values of the internal pressure, calculated as $(\partial U/\partial V)_T$. The most convenient way of evaluating this for the normal melting temperature (p = 0) is to write it in the form[12]:

$$\left(\frac{\partial U}{\partial V}\right)_T = \frac{\gamma C_v T}{V} \quad (\gamma = \text{Grueneisen constant}). \; (3)$$

We obtain the right order of magnitude, and column 4 shows that the ratio of α to $(\partial U/\partial V)_T$ averages 1·5$_2$. If we now calculate the internal pressure for iron according to equation (3), a value of 110,000 atm. is found at the melting point (T = 1,805° K.). Assuming the same ratio as with the alkali metals, we obtain α = 170,000 atm. and therefore c = 3·5. We choose as the most probable set of values one intermediate between the two, namely, c = 4 and α = 150,000 atm.:

$$p_{\text{atm.}} = 150{,}000 \, [(T/1{,}805)^4 - 1]. \qquad (4)$$

For very high pressures equation (4) reduces to:

$$p_{\text{atm.}} = 1 \cdot 4 \, (T/100)^4 \, ;$$

at 1,000,000 atm., for example, this involves an error in T of less than 4 per cent. (*Note added in proof.* I understand from Sir Edward Bullard that he also has applied equation (1) to the melting curve of iron and arrives at similar results. His calculations are to be published early next year by the Chicago University Press in Chapter 3 of Volume 2 of "The Solar System", edited by G. P. Kuiper.)

The validity of equation (4) rests on a few assumptions. The first is that the body-centred cubic δ modification of iron which is stable in the region of the normal melting point continues to be so at higher temperatures. This should be a reasonable assumption; but even if there is a transition to another modification, the only result would probably be a slight decrease in the slope of the melting curve. The second qualification is that no critical point between the solid and fluid phase intervenes: this seems to be justified by the fact that we have solidified a number of substances at very much higher *relative* temperatures[8,13]. Finally, equation (4) would probably cease to be valid if a change in the configuration of the electrons in the outer shell of the iron atom should occur at very high pressures.

Table 2 gives the melting temperatures calculated from equation (4) for a number of pressures, while, to indicate possible limits of error, values calculated with c = 3·5, α = 170,000 atm. as well as c = 4·5, α = 133,000 atm. have been included.

Table 2

	c = 3·5 ; α = 170,000 atm.	c = 4 ; α = 150,000 atm.	c = 4·5 ; α = 133,000 atm.
p (10^6 atm.)	T (°K.)	T (°K.)	T (°K.)
0·1	2,060	2,050	2,040
0·2	2,250	2 230	2,210
0·5	2,670	2 600	2,550
1·0	3,120	3,000	2,900
1·5	3,460	3 290	3,150
2·0	3,730	3 510	3,340
2·5	3,970	3,700	3,500
3·0	4,170	3 860	3,640
3·5	4,340	4 010	3,760
4·0	4,500	4 140	3,870

If the core of the earth consisted of *pure* iron, the equilibrium temperature at the discontinuity at 5,000 km. depth would follow from equation (4) as 3,900° K.; at the centre of the earth the temperature would have to exceed 4,000° K. in order to obtain a core of pure iron in the liquid state (both temperatures are subject to the probable error indicated in the table).

The limitations of our extrapolation need scarcely be emphasized. The best way of arriving at a more secure prediction would be to measure the melting pressures up to values which permit the determination of the curvature of the melting curve. This would imply measurements up to at least 100° above the normal melting temperature corresponding to pressures of about 40,000 atm.; it is evident that no such experiments can be expected in the near future. The second best way for narrowing down the limits of error seems to lie in a better theoretical understanding of the interrelation of the constants of formula (1) and the properties of the single phases. Until this is achieved, the values given above seem to me to constitute the best possible estimate.

THE R.A.F. MOBILE HEARING RESEARCH UNIT

By Air Vice-Marshal E. D. D. DICKSON, C.B., C.B.E., and L. J. WHEELER

Acoustics Laboratory, Department of Otorhinolaryngology, Central Medical Establishment, Royal Air Force

INTENSE noise is a by-product of the mechanical age in which we live, and prolonged exposure to it is liable to affect hearing adversely. The effect will vary with the individual according to his auditory susceptibility. In the early stages of acoustic trauma the hearing mechanism becomes temporarily fatigued but will usually recover; ultimately, what was once a temporary fatigue is liable to become permanent, with definite damage to the hearing mechanism, and thus deafness ensues.

The possibility that the noise of modern aircraft (which includes jets) may affect the hearing of aircrews has been investigated in the laboratory, but no data are available of the effect on aircrews flying under operational conditions. We have planned, developed and had constructed a mobile otological research unit—the first of its kind in Great Britain—which will enable us to test the hearing of aircrews within a few minutes of their stepping from the aircraft.

Hitherto, the post-flight hearing was tested as soon as possible after landing. This was carried out by audiometry in any room conveniently near the 'tarmac'—at the quickest ten to fifteen minutes after landing. As recovery from the effects of noise sets in very soon after the noise has ceased, this time-lag between landing and testing has distorted any results previously obtained of the immediate post-flight conditions. Now it will be possible to drive up to the aircraft as it rolls to a standstill and start hearing tests immediately; the test conditions will also be standardized from the point of view of background noise in the testing room. The results thus obtained will be a more accurate estimation of the effects of flight.

In brief, the Research Unit (Fig. 1) is mounted on a 7-ton Bedford general-service chassis and consists of two compartments, namely, a triple-walled sound-proof cell and an ante-room. In the ante-room the subjects' ears can be clinically examined, while in the sound-proof room hearing tests by audiometry can be carried out. The latter room is comparable to that in use at the Central Medical Establishment, Royal Air Force.

Construction Details

A plan view of the unit, excluding the vehicle cab, is shown in Fig. 1. The major part of the construction consists of oak planks which are tongued and grooved together. The outer walls are diagonally braced with steel bars across their inner surface to give added rigidity. To give some absorption of internally generated noises, the ceilings, all walls and doors of both compartments have a surface of perforated 'hardboard' backed by 'fibreglass', and both floors are covered with 'Airtread' rubber flooring.

The inner room—the test room—has a three-thickness assembly for walls, floor and ceiling. The spaces between the walls and between the ceilings are filled with hair felt; those between the floors with fibreglass quilting. At no point does this inner cell come into direct mechanical contact with any other part of the structure. Double doors give access to it from the ante-room.

The subject when under test can be seen through the sealed plate-glass double window in the walls common to the ante-room.

Beneath the window in the test room is a shelf on which is the Morse key by which the subject signals to the tester in the ante-room.

The ante-room has, except for the dividing walls between it and the inner cell, only one wall thickness; but the floor is raised by deep joists and extra thicknesses of quilted fibreglass to the level of that of the inner cell.

The ante-room contains the audiometer, all clinical instruments and the apparatus required to check and maintain the calibration of the audiometer. The clinical instruments are carried in drawers beneath the glass-topped shelf and the calibration apparatus in a lower cupboard beneath the drawers.

On the wall away from the inner cell a Chiron bull's-eye examination lamp is fitted. Above that is a ventilation fan of the extractor type; it can be covered when testing is in progress in order to present a uniform wall surface.

Equipment

The audiometer used is of the pure tone type and has been designed, constructed and calibrated in the Acoustics Laboratory of the R.A.F. Central Medical Establishment. The calibration and performance fulfil the requirements of the latest specification for pure tone audiometers.

Since the vehicle is entirely self-contained, it is independent of external power supplies. The power for all the equipment is provided by two 12-V. aircraft starter batteries mounted on a platform forward of the test room. These have three uses: (1)

to drive a rotary convertor to produce 230 V. A.C. for the operation of the audiometer, its calibrator and the Chiron lamp; additional outlet sockets are provided for a soldering iron or other equipment; (2) to drive a vibratory transformer to produce 90 V. A.C. for the six 15-W. fluorescent lights—four in the ante-chamber and two in the test chamber; (3) direct, for the operation of the 24-V. D.C. extractor fan.

A 360-W. petrol-driven charging set for the accumulators is also installed. This charging set, the rotary transformer, interference suppressors and the vibratory transformer are all carried with the accumulators on the platform between the chamber itself and the vehicle cab. All are fitted with weather-proof metal covers, while that of the rotary convertor is also lined with sound-absorbent material.

Beneath this platform distilled water for the accumulators, a test meter and all small tools are carried in two rubber-lined weather-proof lockers.

OBITUARIES

Dr. B. Mouat Jones

THE announcement of the death of Dr. B. Mouat Jones on September 11 at the age of seventy came as a great shock to all who knew him. Since his retirement in 1948 he had led a most active life, and right up to the last he seemed to be in better physical condition than most men ten years his junior.

Educated at Dulwich and at Balliol College, Oxford, where in 1905 he took a first-class honours degree in chemistry, mineralogy and crystallography, Mouat Jones followed a brief appointment at the Imperial Institute by a seven-year sojourn in India as professor of chemistry at Government College, Lahore. In 1913 he returned to England to become assistant professor of chemistry at the Imperial College of Science and Technology; but the outbreak of war put an end to this phase of his career and he enlisted at once as a private in the London Scottish. It was not long, however, before Prof. W. Watson selected him to become his assistant director at the Central Laboratory G.H.Q., in France, there to participate in countering the German onslaught of gas warfare. In this, where speed was of paramount importance, Mouat Jones was remarkably successful; and worthy of special mention in this connexion were his devising of methods of protection from phosgene gas and his rapid identification of what by a curious accident became known as 'mustard' gas. By the end of the War he was the director in charge of the laboratory with the rank of lieutenant-colonel, and with the D.S.O. and three mentions in dispatches to his credit.

Returning to civilian life, he held for a short period the chair of chemistry at Aberystwyth; but in 1920 he was elected principal of the Manchester College of Technology, where he spent the next seventeen years of his life. The outstanding success with which he held this office can only be properly appreciated by those thoroughly acquainted with the nature of his task, and with the form of the concordat between the University and the City which established the College as the Faculty of Technology in the University of Manchester. It is perhaps only necessary to say here that the success with which harmonious working relationships were established among all those concerned was due in a very large measure to the impact and influence of those personal qualities with which Mouat Jones was so exceptionally gifted: high moral courage and integrity, firmness of purpose, human understanding and a strong sense of humour, and perhaps, above all, an unshakeable faith in the future of technology as a vital part of the university system of Great Britain.

Being by nature modest and retiring, he accepted with some trepidation the invitation in 1938 to succeed Sir James Baillie as vice-chancellor of the University of Leeds; but there again the same personal qualities carried him through an exacting ten years term of office with conspicuous success. Not only had he to guide the destiny of the University through the difficult war-time years, but also by wise judgment and strict impartiality to keep the University on an even keel during the even more difficult years of rapid expansion which followed.

In addition to the formal duties of his several offices, and before and after his retirement, Mouat Jones served the State, the Commonwealth and his fellow-men in a great variety of ways—too many to detail in this short notice; but by all those who had the good fortune to know him he will be remembered not so much by what he did as for what he was. He had his enemies, as nearly all men must who hold high office; but his friends and admirers were legion. Though not naturally gregarious, he was one of the most approachable of men and won the high regard and warm affection of an astonishingly large number of those of all degrees who in one way or another came under the influence of his personality. By those who met him casually at public dinners and similar functions, he will be long remembered as one of the wittiest and most accomplished of public speakers; but to his one-time colleagues and associates and also to his innumerable old students now spread over the four quarters of the globe, his passing is that of a trusted and irreplaceable friend. W. E. MORTON

The Duke of Bedford

THE twelfth Duke of Bedford, whose death at the age of sixty-four has occurred, had other activities than those connected with Evangelical Christianity, social work, monetary reform and the kindred subjects by which he was best known to the public. His interest in zoology was of the keenest. His father and mother left at Woburn a fine collection of deer, bison, waterfowl, etc., and this collection he not only maintained but also enhanced. He knew his animals intimately, as was apparent when he took me around the park in August last. We paused to look at a number of red deer. He pointed out the different stags and told me their ages and details of their careers.

The unique herd of Père David's deer were his special delight. This large donkey-like species, which is exterminated in its native China, is represented only by the three or four hundred animals at Woburn and a few the Duke sent elsewhere. There are no others in the world. It is thanks to the Duke of Bedford it survives. He was also proud of his European bison and showed me with delight the new bull he had obtained with much trouble from Sweden. Seeing how precarious is the position of this species on the Continent, zoologists must again be grateful for the sanctuary afforded the individuals at Woburn.

The Duke of Bedford was also an ornithologist, having made a life study of the parrots and allied birds. Prior to the War he had a remarkable collection of such birds; but war-time difficulties led to its reduction. However, when war ceased he again got together many rare and little-known species. His book on "Parrots and Parrot-like Birds in Aviculture" is an authoritative work.

One of his special joys of recent years was to watch his "liberty budgerigars". It was indeed a lovely sight to see a number of these butterfly-like birds flying free.

Not only was the Duke of Bedford a practical zoologist and ornithologist but also nothing gave him more pleasure than to assist others with like interests. He was ever ready to help, being kindness itself to many a young naturalist.

FRANCES PITT

WE regret to announce the following deaths:

Prof. C. Białobrzeski, formerly professor o theoretical physics in the University of Warsaw aged seventy-five.

Mr. P. E. Negretti, chairman and managin director of Negretti and Zambra, Ltd., on Septembe 20, aged seventy.

Prof. W. M. Roberts, O.B.E., lately professor o mathematics in the Royal Military Academy, Woolwich, on October 16.

Dr. L. F. Richardson, F.R.S., formerly principa of Paisley Technical College, on September 30, age seventy-two.

NEWS and VIEWS

Geology at the University College of North Staffordshire: Prof. F. Wolverson Cope

THE University College of North Staffordshire, at Keele, was opened in 1950 with thirteen professors. The academic staff now numbers more than eighty, and two new chairs—of classics and geology—have recently been created. Each of these posts goes to the reader in the subject, and the new professor of geology is Dr. F. Wolverson Cope. Educated at King's School, Macclesfield, and the University of Manchester, Dr. Cope served in H.M. Geological Survey from 1934 until 1950. He is a field geologist primarily, his main work having been on the stratigraphy and palæontology of the Carboniferous system, especially in Staffordshire, Derbyshire, Lancashire and North Wales. His research has on two occasions earned awards from the Geological Society of London. His work in south-west Lancashire was directly responsible, in 1939, for the discovery of a small oil-field at Formby. In the North Staffordshire coalfield, he was largely responsible, while with the Geological Survey, for the six-inch re-mapping, and his considerable local experience, both above and below ground, in this field is a particularly valuable asset to his work at Keele, where in three years he has built up a large department (soon to move into new premises). In an academic curriculum in which some science is insisted on for all students, geology is a popular subject; but Dr. Cope has also a flourishing honours school, and is contributing to the training of geographers, who are required to take a year's geology.

Technological Education in Great Britain

IN an address to the Union of Lancashire and Cheshire Institutes given at Lancaster on October 2, Mr. Lincoln Gordon, minister for economic affairs at the American Embassy, London, and chief of the United States Foreign Operations Administration Mission to the United Kingdom, suggested that even if all the various means of expanding technological education—by the expansion of existing technological departments of universities, development of existing technological colleges, or the establishment of one or more independent institutions on the lines of the Massachusetts Institute of Technology—were pushed to the furthest practicable limits, the resulting expansion would not surpass the ever-growing needs. The best technological training in Britain, he said, is second to none; but technological education should also reflect the growing part of the engineering profession as a source of general industrial management: education for management should become an important adjunct of higher technological training. Mr Gordon is convinced that the science and art o management could, in large and increasing measure be analysed, systematized and communicated t others: administration could be a genuine discipline. Properly handled, the case method can greatly enhance the student's ability to assume practical responsibilities and to contribute constructively t the operation of his firm. However, young men and women who have several years of experience in industry or business, owing to that background and their greater maturity, are much better students o administrative subjects than those newly graduated; there are other advantages, too, such as the elimination of wastage, and an earlier start on a useful career, when entry on such courses is deferred. Mr. Gordon also suggested that Britain might have something to learn from American experience in providing a greater number of intensive short-term courses, similar to those already existing at the Administrative Staff College, Henley, for men with ten to twenty years of experience in industry who might be considered for promotion to the highest posts of general management.

Science Teachers in Scotland

THE Secretary of State for Scotland has appointed the following committee to advise him on the supply of mathematics and science teachers in Scotland: Sir Edward Appleton (*chairman*); Prof. E. T. Copson, professor of mathematics, University of St. Andrews; Prof. J. M. Graham, Lord Provost of Aberdeen; Mr. A. G. McKimmie, headmaster of Allan Glen's School, Glasgow; Dr. A. R. Murison, rector of Marr College, Troon; Dr. H. B. Nisbet, principal of Heriot-Watt College, Edinburgh; Mr. H. P. Wood, director of studies, Jordanhill Training College, Glasgow; and Mr. A. L. Young, director of education, Aberdeenshire.

Oil Pollution Research: Plotting of Currents in the North Atlantic

THE National Institute of Oceanography will shortly initiate an intensive research into the surface currents in the North Atlantic to the west of the British Isles as part of the campaign against the pollution of the beaches of Britain by oil residue jettisoned by ships. It is planned to drop into the sea some ten thousand plastic envelopes, each containing a numbered card carrying the date and position in which each is dropped. Finders will be asked to write on the postcard their name and address, and the date and place of recovery of the envelope. The instructions will be printed in eight different languages. A reward of half-a-crown, or its equivalent in foreign currency, will be paid to the sender of each postcard which is received by the National Institute of Oceanography, Wormley, near Godalming, Surrey. Dropping will be carried out from Coastal Command aircraft on navigational training flights. The dropping track will run from the Bay of Biscay, roughly in a semicircle of 500 miles radius, to a point halfway between the Hebrides and Iceland, and will thus stretch from side to side of the belt of current travelling north-east which crosses the Atlantic in these latitudes. In order to learn more about seasonal changes in the currents, about two thousand envelopes will be dropped in early spring, autumn and winter of 1954; double that quantity will be released in early summer, when the chances of recovery by holiday-makers between one and three months later will be greater than during the other seasons. The dates on which the envelopes will be dropped will be announced later.

Radio Observations of Meteor Streams

Two of the papers in Astronomical Contributions from the University of Manchester, Series 1: Jodrell Bank Annals (1, No. 2, 13; December 1952) deal with the radio-astronomical work at Jodrell Bank on meteors. The first paper, by Mary Almond, K. Bullough and G. S. Hawkins, with the title "Radio Echo Observations of the Daytime Meteor Streams in 1952", is a continuation of the work of previous years on the daylight meteor streams. The same equipment as was formerly used was utilized for measuring meteor velocities, the accuracy of an individual determination being ± 5 per cent, and radiants were delineated with an accuracy of ± 1° in right ascension and ± 1·5° in declination. Five tables give the necessary information on such matters as mean hourly rate, maximum hourly rate, meteor velocities, etc., and the following interesting points emerge as a result of the work. As the η Aquarid radiant appeared in its normal position at the expected value of the sun's longitude, it is assumed that the anomalous displacement of 20° observed during 1951 was probably due to a spurious grouping of sporadic meteors. The mean radiant position, mean velocity and orbital elements of the daytime Arietids are compared with those obtained during 1950 and 1951, and the results are in good agreement. A mean ephemeris for the motion of the radiant of the daytime Perseids, combining the results for 1950–52, shows that this motion, and hence the structure of the stream, are similar to those of the daytime Arietids. The ephemeris of the radiant motion of the daytime β Taurids, obtained by combining the results for 1952 with those for the previous two years, shows that the motion is eastward and towards the ecliptic. The mean orbit again confirms the close association of this stream with the night-time Taurid stream and Encke's comet. The second paper, by Mary Almond, deals with the observations made during July 1952 to determine the velocity of the δ Aquarid meteors, and the mean velocity has been used to compute an orbit which has a strong resemblance to that of the daytime Arietids. The orbits of both streams, projected on the plane of the ecliptic, are shown. Calculations show that the δ Aquarids are 0·31 astronomical unit away from the earth at the second approach on June 9 and that the width of the daytime Arietids must be at least 0·27 astronomical unit. It is considered probable that the connected showers are produced by one extended stream.

Earthquake Damage and the Nature of the Ground

The relation between earthquake damage and the nature of the ground has been examined by Kiyoshi Kanai, Teiji Tanaka and Tomisaburo Suzuki in a recent paper on this subject (*Bull. Earthquake Res. Inst. Tokyo Univ.*, 31, Pt. 1, 57; March 1953). The earthquake considered was the Tokachi-Oki one of March 4, 1952, which had an instrumental magnitude of 8·1. The numbers of totally destroyed, semi-destroyed and slightly damaged houses in the south and east parts of Hokkaido were about 1,400, 5,400 and 15,000, respectively. The main public buildings were damaged more seriously than ordinary houses, since the upper parts of the houses in Hokkaido are very light. Destruction occurred in an area in which peat covered a clay sub-soil, though the destruction in an area surrounding a point (A) 2·2 km. south-south-west of Iked station was not so great as in an area surrounding a point (B) 2·9 km. south-west of the station. A geophysical prospecting survey gave the following results.

Place	Velocity of P-waves (m./sec.) First layer	 Second layer	Thickness of first layer (m.)
A	350	1,400	15
B	150	1,800	2

The largest amplitude at a free surface is caused by a wave of which the period is equal to the natural one of the object under consideration. With the above results and assuming that Poisson's ratio in both layers is 0·48 and that the densities of materials in the layers are 1·5 and 2·0 gm./cm.^{3}, respectively, then ξ/v^3 for (A) is $7 \cdot 6 \times 10^{-7}$ c.g.s. units and for (B) is $15 \cdot 2 \times 10^{-7}$ c.g.s. units. Assuming the amplitude in any period of incident waves at the boundary to be constant, the ratio of surface ground displacements $A : B$ is 2 : 1, and the ratio of the surface accelerations $A : B$ is 20 : 1. Assuming equipartition of energy for waves of different periods, the ratio of amplitudes (displacements) $A : B$ is 0·62 : 1 and ratio of surface accelerations $A : B$ is 6·2 : 1. Hence the periods of the waves at (A) and (B) which have predominant amplitudes become $4H/v_s = 0 \cdot 0$ sec. ($\equiv T_A$) and 0·3 sec. ($\equiv T_B$). The natural period of top-light farm-houses peculiar to Hokkaido appears to have been approximately 0·3 sec., and thus according to the above work, in the case of a great earthquake, the houses in (B) district would be under worse vibrational conditions than those in (A) district—as was observed.

Geological Structure of the Russian Platform

Dr. S. I. Tomkeieff has rendered a valuable service to geologists by summarizing recent work in the U.S.S.R. on the structure of the Russian Platform; his paper (*Proc. Geol. Soc. London*, July 15, p. 108) is accompanied by a map of the pre-Devonian surface of the Platform. Karpinski's conception in 1886 was that the Lower Palaeozoic deposits extended from the Baltic Sea region across the Platform in an easterly direction towards the Urals. During recent years, using the data provided by a large number of borings, Shatsky has made this conception more precise and has recognized the existence of a comparatively shallow downwarp of the Platform—designated the Moscow 'syneclise'—extending from the Baltic Sea between Leningrad and Moscow and then turning sharply to the north. The unmetamorphosed Pre-Cambrian rocks which form the lowest part of the sedimentary cover of the Platform are called by Shatsky the Rhiphæan Group. The transgression of the Cambrian over the latter can be traced all along the border of the Fennoscandian Shield; thus the Rhiphæan is apparently equivalent to the Eocambrian or Sparagmitian of Norway. Shatsky even wishes to apply the term Rhiphæan to other similar deposits, such as the Sinian, found in China, Siberia, India and elsewhere; but in the absence of palæontological means of correlation, it is obvious that local names cannot yet be superseded. Shatsky's map shows the Rhiphæan–Lower Palæozoic syneclise (downwarp) separating the Baltic and Sarmatian Shields. The latter is divided by a narrow Rhiphæan trough into the Uralian–Volga massif on the north-east and the Kiev–Voronesh massif on the south-west.

Synthetic Materials in Picture Conservation

An important paper in the September issue of the *Museums Journal*, by Arthur Lucas and Norman Bromelle, of the National Gallery, London, deals with the failure of certain synthetic materials in picture conservation. They maintain that during the past few years a number of statements have appeared in the national and technical press which give the impression that newer materials discovered by the organic chemist are superior to the traditional varnishes, media and adhesives used hitherto. This paper has been written to warn restorers and conservators of the dangers incurred in accepting recommendations from partisans of the products of modern chemical industry. Mr. Lucas and Mr. Bromelle believe that modern synthetic materials have not fulfilled their promise for probably two reasons. First, the natural materials, glue, egg, natural resins, etc., are invariably complex in composition, each containing a large range of different substances often highly complex in themselves; in the process of forming, say, an adhesive bond, these different ingredients all play their part in reinforcing each other, so that in all the variations in surface properties of the parts to be attached the glue is sufficiently versatile to adapt itself. Secondly, a picture is composed of layers of wholly natural materials, apart from the pigments, and its response to external conditions (temperature, humidity, etc.) depends on the combined physical properties of these materials; the natural materials used in conservation can be made to harmonize readily with these properties, but the harmony is far more difficult with artificial materials. Full details of many of these new synthetic materials and their reactions are given in the paper quoted.

The Musk-Ox

First recorded by an English youth so long ago as 1689, the musk-ox forms the subject of an interesting article by R. Glover in a recent issue of *Oryx* (2, No. 2). The musk-ox is a little-known Arctic mammal. Generally, these animals feed on moss but, when this is scarce, have been known to feed on the young twigs of willow, pine and even elm trees. They are gregarious, and each cow probably produces one calf every two years. One of the natural enemies of the musk-ox is the wolf; to resist attack by the latter, musk-oxen often stand, horns outward, in a bunch, practising a characteristic defensive drill. Apart from the use of the skin as warm robes, the animals have suffered little commercial exploitation by man and, although the musk-oxen have disappeared from wide areas they once inhabited, adequate stocks still remain. At present there are some prospects of domesticating the animal and this is causing some speculation in North America. Mr. Glover believes that the best way of making the musk-ox serviceable to mankind is not by domestication but by intelligent game management in its native home.

The Philosophy of Numbers

In a communication to the Eleventh International Congress of Philosophy, held in Brussels during August 20–26, Prof. D. Riabouchinsky gave a summary of the ideas he has developed and published in a series of papers for forty years. His communication, which is entitled "La Définition des Nombres par leur Valeur numérique et par leur Origine; Rôle de ce Concept en Philosophie mathématique", is published in Vol. 5—Logic, Philosophical Analysis, Philosophy of Mathematics—of the proceedings of the Congress (Amsterdam: North Holland Publishing Co.; Louvain: Éditions E. Nauwelaerts, 1953). The ideas presented are so different from those usually held that they have been misunderstood or rejected without examination. The author does not consider two numbers as equal, even if they have the same numerical value, if they arise in a different manner: for example, $\sin \pi/2$ and $\sin 5\pi/2$, both of which have the numerical value 1. Moreover, he distinguishes between Euclidean points, which are the extremities of lines, and dimensional points, which are the limits obtained by reducing to zero a length, surface or volume. The importance of this distinction is that it leads the author to reject certain well-known theorems in the theory of sets, such as Cantor's theorem that the number of points in a square is equal to the number in one of its edges. Another aspect of the author's point of view, and one more difficult to understand, is a theory of a new kind of imaginary numbers, which is associated with a principle attributed to Kant. He has also a general theory of algebraic equations which contain the symbol for absolute value, but details are not given here.

Research on Kilns in Japan

Among the various topics discussed in Bulletin No. 60 of the Government Forest Experiment Station (Meguro, Tokyo; March 1953) various aspects of the kilns used in Japan are considered. Experiments are being made with different types of charcoal kilns in four different provinces in Japan, and the methods of construction are outlined. Other experiments are connected with drying-kilns. Before the Second World War most of the kilns in Japan were of the natural ventilated type, its inadequacy being due to the impossibility of drying the boards evenly and quickly. After the War, the Sturtevant kiln was built, but its use in Japan has not apparently been satisfactory. The faults that have been discovered and the tests made on the kiln are all described in the bulletin.

Indian National Scientific Documentation Centre : Report for the Year 1952–53

This first annual report, for the year 1952–53, of the Indian National Scientific Documentation Centre has now been published (pp. 13; from the Centre, New Delhi, 1953). The Centre was set up on July 7, 1951, under an agreement with the United Nations Educational, Scientific and Cultural Organization, providing for technical assistance over three years. It is situated in the National Physical Laboratory of India, New Delhi, and is under the administrative control of Sir K. S. Krishnan, assisted by an advisory committee. All possible steps are being taken to obtain and hold copies of scientific periodicals required in India, particularly by the universities, scientific research organizations and government laboratories, and the Centre is now in a position to supply to any country a copy of an article published in any Indian scientific periodical. Other functions of the Centre are to prepare an index of periodicals available, to act as a national repository for reports of Indian scientific work, to deal with inquiries, and generally to act as a means of making the scientific work of India and the surrounding countries known and available to the rest of the world. Three scholarships were provided by Unesco during 1952 for training suitable candidates in special fields of study relating to the project. The information service has been organized and the translation service supplemented by a panel of translators on which twenty-three persons are at present enrolled, and it is proposed to issue a monthly bibliographical bulletin giving the titles of scientific papers published in Indian and foreign periodicals and a list of translations available.

Current Periodicals in the Science Library, London

The seventh edition of the "Hand List of Short Titles of Current Periodicals in the Science Library" (pp. 388; London: H.M.S.O., 1953; 10s. net), which was first published in 1904, contains about 8,500 titles of periodicals now being received, compared with the 7,000 entries of the sixth edition (1950). The order of entries is that of the "World List of Scientific Periodicals", with the exception that periodicals which have distinctive titles commencing "Journal", "Bulletin", etc., follow journals, bulletins, reports, etc., of societies, institutions, etc., and do not appear in one alphabetical order. Thus, the "Journal of Allergy" is not placed between "Journal, Alabama Academy of Science" and "Journal, American Ceramic Society", but after "Journal, Yorkshire Agriculture Society". In all entries, the dates following the semi-colon are dates of publication; but the range of years covered by a single report, and the years covered by runs and any gaps in a series of volumes, are also indicated. There are no cross-references, but extra entries are made under alternative forms of the title; and although a periodical is entered only under its current title or titles, the heading shown is inclusive of its earlier titles. Shelf-marks are given at the end of the entries and should be quoted by all users of the list so as to expedite service.

Finances of the United States National Science Foundation

A further inquiry by the National Science Foundation indicates that Federal agencies in the United States spent 1,839 million dollars on scientific research and development during the fiscal year 1952, the corresponding estimate for 1953 being 2,189 million dollars, and the president's budget of January 9 included 2,327 million dollars for the year 1954. During each of these years funds administered by the Department of Defense amounted to 72 per cent of the total, compared with the 14 per cent for the Atomic Energy Commission and 4 per cent for both the National Advisory Committee for Aeronautics and the Federal Security Agency. During 1952, 307 million dollars was allotted for increase of existing research facilities or construction of new laboratories, 198 million dollars of this going to the Department of Defense and 60 million to the Atomic Energy Commission.

University of Sheffield

The United Steel Companies, Ltd., have established a research fellowship in metallurgy in the University of Sheffield, tenable in the Department of Metallurgy, the object of which will be to advance metallurgical knowledge and not to train persons for research. Appointments to the fellowship will be made from time to time from among scientific workers who have already served their apprenticeship in research and have shown ability to conduct independent investigations. The field of study within which they will be expected to work will be ferrous metallurgy, but this does not exclude the appointment of researchers in refractory matters, knowledge of which is of great importance in ferrous metallurgy. The fellowship will be worth at least £750 for the first year, rising by annual increments of £50, and will be normally held for five years.

The following have been appointed lecturers in the University of Sheffield: K. H. Sutherland and E. P. Bernat (mechanical engineering); Dr. W. Eastwood and C. Osgerby (civil engineering); and F. G. West-Oram (glass technology).

Institute of Navigation: Officers for 1953–54

The following have been elected officers for 1953–54 of the Institute of Navigation: *President*, D. H. Sadler, superintendent of H.M. Nautical Almanac Office; *Vice-Presidents*, Air Chief Marshal the Hon. Sir Ralph Cochrane, formerly Vice-Chief of the Air Staff, and Captain F. J. Wylie, R.N. (ret.), director of the Radio Advisory Service; *Honorary Treasurer*, Francis Chichester; *Chairman of the Technical Committee*, Wing Commander E. W. Anderson; *Chairman of the Executive Committee*, Captain G. C. Saul, deputy master of the Honourable Company of Master Mariners.

Colonial Service: Recent Appointments

The following appointments have recently been made in the Colonial Service: R. B. Allnutt (assistant director of agriculture, Nigeria), deputy director of agriculture, Western Region, Nigeria; M. A. G. Hanschell (agricultural officer, Sierra Leone), development commissioner, St. Lucia; C. A. S. Hynam (agricultural officer, Trinidad), agricultural officer, British Honduras; A. Jefferies (agricultural officer, Tanganyika), director of agriculture, Seychelles; E. A. Tai (senior agricultural officer, Jamaica), agronomist, Trinidad; E. H. Jaques (geologist, Federation of Malaya), principal geologist, Federation of Malaya; H. E. F. Savage (principal geologist, Federation of Malaya), deputy director, Geological Survey, Federation of Malaya; G. H. S. Wood (assistant conservator of forests, Uganda), senior scientific officer, forest botanist, North Borneo; E. Millington (senior agricultural survey officer, Gold Coast), principal agricultural survey officer, Gold Coast; V. I. Mulloon (senior agricultural assistant, Trinidad), soil survey officer, Trinidad; R. M. S. Neave (veterinary officer, Kenya), chief veterinary officer, Cyprus; E. Pienaar (field officer (agriculture), Tanganyika), superintendent of agriculture, Tanganyika; C. M. Taylor (education officer, Kenya), meteorologist, East African Meteorological Department, East African High Commission; R. J. R. Barrett, G. I. M. Martin and C. R. Raper, agricultural officers, Federation of Malaya; P. A. P. Dawson, geologist, British Solomon Islands Protectorate; A. J. Crosbie, soil survey officer, Department of Soil and Land Use Survey, Gold Coast; J. C. Duerden, scientific officer, Nigeria; W. R. V. Lort, cultivation officer (Department of Science and Agriculture), Barbados; J. A. Spence, plant pathologist, British Guiana; R. M. Thompson, geologist, British Solomon Islands Protectorate.

Tenth World's Poultry Congress, Edinburgh

The Tenth World's Poultry Congress will be held in Edinburgh during August 13–21, 1954, under the auspices of the World's Poultry Science Association, and will be organized by the Department of Agriculture for Scotland. For the sessions on the reading of papers the Congress will be divided into five sections covering the following topics: genetics and breeding; physiology and nutrition; diseases and their control; economics and marketing; and husbandry and miscellaneous. Any person may submit a paper to be read at the Congress, whether or not he is a member of the World's Poultry Science Association. Papers should be 1,500–3,000 words in length, written in English or French, and must be accompanied by a résumé not exceeding 300 words in the same language. Those intending to submit papers should send in the title to the Congress Secretariat before October 31, 1953, and the full text before January 1, 1954. Further information can be obtained from the Secretariat, Tenth World's Poultry Congress, St. Andrew's House, Edinburgh 1.

Origins of Resistance to Drugs: Symposium in Washington, D.C.

A symposium on the origins of resistance to drugs, etc., is being organized by the United States Office of Naval Research and the University of Pennsylvania and will be held in Washington, D.C., during March 25–27, 1954. The symposium will consist of five successive sessions devoted, respectively, to the following topics: the origins of microbial drug resistance; tolerance and addiction to drugs, and alcoholism; resistance to insecticides and herbicides; factors in resistance to infectious agents, the biochemical mechanism of carcinogenesis and the nature of tumour immunity; and a concluding session devoted to the integration of the questions of resistance from the genetic, physiological and chemical points of view. Papers will be given by invited speakers, followed by open discussion from the audience. Application forms and further information can be obtained from Dr. M. G. Sevag, Department of Microbiology, School of Medicine, University of Pennsylvania, Philadelphia 4, Pennsylvania.

International Council for Electrodeposition: Conference in London

At the first meeting of the newly constituted International Council for Electrodeposition, which was held recently in London at the headquarters of the Institute of Metal Finishing, plans were laid for the forthcoming international conference to be held in London during April 21–24, 1954. A large number of overseas delegates are expected to attend, in particular a strong contingent from the United States, and it is hoped to organize a special session to discuss the latest American practices in electrodeposition. The Institute of Metal Finishing has arranged that on the eve of the international conference the Hothersall Memorial Lecture for 1953–54 will be given by Dr. William Blum, who is well known in the field of electrodeposition through his study of electrochemical processes and other problems. Membership of the International Council is open to technical societies and institutes throughout the world with interests in the field of electrodeposition. They are invited to write in the first place to the honorary corresponding secretary of the Council, Dr. S. Wernick, Institute of Metal Finishing, 32 Great Ormond Street, London, W.C.1.

Glassware for the Laboratory

Two well-known British manufacturers of laboratory glassware have recently published catalogues which should be of interest to a wide range of scientific workers. One of the firms, Quickfit and Quartz, Ltd. (Heart of Stone Works, Staffs), has a list giving the prices of apparatus made by them and also an illustrated catalogue giving full particulars. The taper on 'Quickfit' ground-glass joints agrees with that specified in British, American, Belgian, Czech, Dutch, French and German standards. The catalogue also illustrates many assemblies of apparatus which can be made from parts supplied by the firm. The other catalogue is from James A. Jobling and Co., Ltd. (Sunderland, Co. Durham), the sole manufacturer in the United Kingdom of 'Pyrex' laboratory and scientific glassware. The descriptions and prices are given of a large range of apparatus; the joints of parts that can be assembled are interchangeable. The firm will also make special apparatus in 'Pyrex' glass to designs of users.

Announcements

Mr. D. N. Lowe, secretary of the British Association, has been appointed secretary of the Carnegie United Kingdom Trust in succession to Mr. James Wilkie, who is due to retire on March 31, 1954.

A meeting on "Re-establishing Scientific Contacts with the U.S.S.R." will be held under the auspices of Science for Peace at Denison House, 269 Vauxhall Bridge Road, London, on October 28 at 7.30 p.m. Prof. K. Lonsdale will take the chair and the speakers will be Dr. J. S. D. Bacon, Prof. J. D. Bernal, Dr. D. M. Crowfoot Hodgkin, Dr. A. H. Gordon and Prof. J. H. C. Whitehead. Questions and discussion will follow. Tickets (price 1*s*.) can be obtained from Science for Peace, 49 Flower Lane, London, N.W.7.

The Nutrition Panel of the Food Group of the Society of Chemical Industry will be holding a series of meetings during the session 1953–54 under the general title of "Nutritional Appraisals". The first meeting will be held in the Rooms of the Chemical Society, Burlington House, Piccadilly, London, W.1, at 6.30 p.m. on October 28, when Dr. A. E. Bender will discuss proteins. Other meetings in the series will deal with calories and basal metabolism on December 9 and vitamins on January 27. Further information can be obtained from the honorary secretary of the Panel, L. C. Dutton, Virol, Ltd., Hanger Lane, Ealing, London, W.5.

NEW PHYSIOLOGICAL LABORATORY AT OXFORD

A NEW Physiological Laboratory has been built in Oxford, at a cost of £300,000, and is now coming into use. It has been designed by Prof. E. G. T. Liddell, Waynflete professor of physiology in the University, in consultation with the architects, Messrs. Lanchester and Lodge.

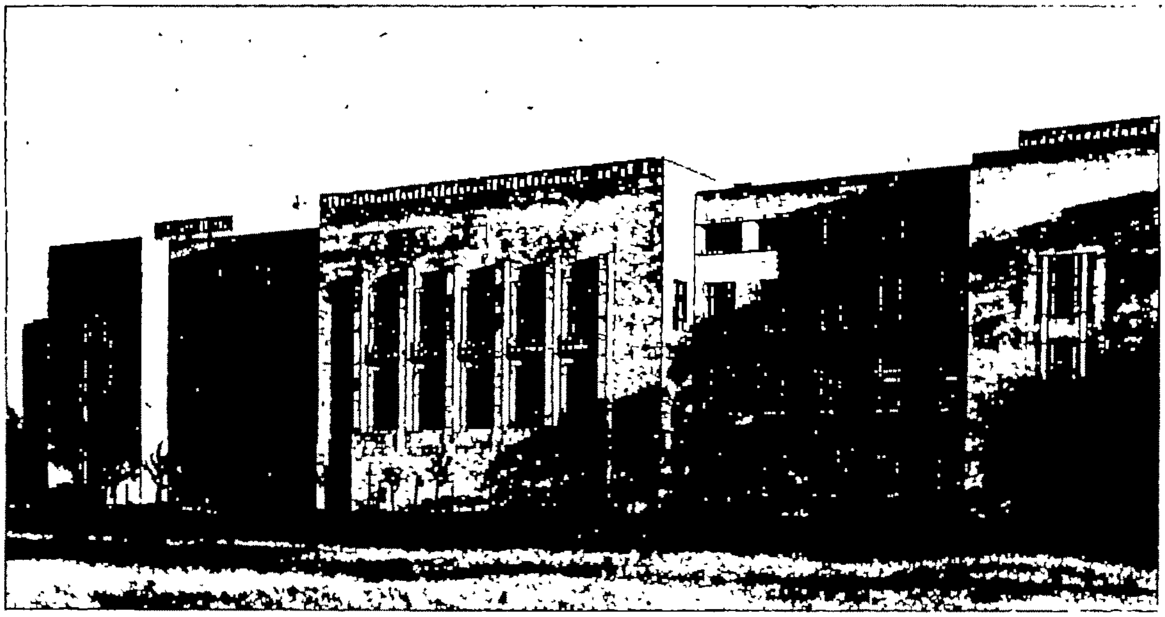
The old laboratory was begun in 1883 and cost £10,000. In those days the annual intake of students was small—seven in 1887. In 1908 a new block for physiological chemistry was added, at a cost of £5,500. The building could then accommodate an optimum number of twenty-five students a year, and in 1914 the number was twenty-six. Severe strain was first felt in the wake of the First World War: the 1923 class numbered 63. In 1926 things were made easier by the foundation of the Department of Biochemistry, in that bench space for the whole of 'chemical physiology' was no longer needed in the old laboratory. But student numbers never fell to the pre-War level: the number of class-meetings attended by each student had to be cut down, classes had to be duplicated, and the need for a new laboratory became every year more urgent. The late Prof. John Mellanby planned a £102,000 building in the late 1930's, but this had to be given up in 1939. The newly built Laboratory will bring relief to students and teachers alike, for the 1952–53 class numbered 79, exceeding by threefold the capacity of the old classrooms.

The new building is of stone-coloured brick. It has four stories, three staircases and goods and passenger lifts. It is long and narrow, 360 ft. long and 75 ft. wide at its centre. This shape, imposed by the shape of the only available site, gives a spurious impression of vastness which can only be corrected by viewing it end-on. It provides bench space for an annual intake of a hundred students. Research accommodation is also increased, but not in proportion to the increased room for teaching.

The main entrance hall and large lecture theatre together fill a large part of the centre of the building, and are two stories high. The lecture theatre seats 250, in fourteen parallel, steeply sloped tiers. At the back are external projection and rewinding chambers, and beneath these a glass-fronted gallery whence late-comers may see what goes on within, and whence they may unobtrusively enter. For demonstrations there is an oval well-shaped theatre with leaning-space for a hundred spectators. Also on the ground floor are two classrooms for muscle–nerve experiments; a darkened classroom for ophthalmic work; the main engineering shop; and four research rooms (one of them screened from electrical interference), with their photographic dark-rooms and office and workshop accommodation.

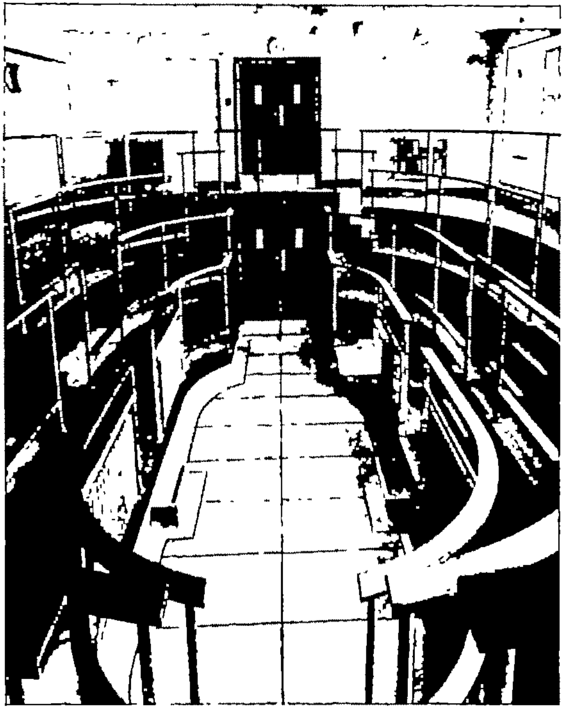
On the first floor are the professor's offices, and two research rooms, with dark rooms, for himself and his associates. Human physiology has two classrooms and three research rooms, one of which incorporates a cold room. The staff common room is on this floor.

The second floor has a small lecture room seating 85; a large classroom for histology, and a smaller one for more advanced histological work for the senior class; classrooms for mammalian physiology and for advanced electrophysiology; the library; and



Thomas Photos, Oxford

Fig. 1. Department of Physiology, University of Oxford



Thomas Photos, Oxford.

Fig. 2. Demonstration theatre

the photographic studio. Research accommodation on this floor comprises three suites of small interconnected rooms adapted to the needs of microscopical work.

The third floor opens out on to a large area of the whole length of the second-floor roof, which can be used for experimental work on muscular exercise, the subjects' courses being timed from the bay windows of a special observation room. On this floor are the operating theatre and X-ray room; an observation room for the psychological testing of small and large primates; and a spacious and well-ventilated animal house, which includes a sound-proofed dog-kennel room.

The Laboratory has been designed with the view of maximum adaptability of purpose. Rooms filled with extensive and permanent bench installations are few, and most of the classrooms and research rooms could be differently divided and furnished from time to time, as changing interests and emphasis may require.

Enough has probably been said to show that Oxford's problem of inadequate bench space for physiology has been solved. Elementary instruction will now be possible without strain; and a start can be made with the re-expansion of the content of the courses in advanced physiology. The extent and direction of this expansion must, of course, depend on the interests of the research workers who form the teaching staff. Its pace will depend on the rate at which financial stringency will allow reinforcement of their numbers to a level which will restore the student–teacher ratios of the senior classes of former days. For there is to be no weakening of the traditional policy which strives to place before the large majority of Oxford medical students educational opportunities which are elsewhere restricted to men and women proposing to specialize in biological research.

NINTH INTERNATIONAL CONGRESS OF GENETICS

THE post-war trend in international scientific meetings has been towards small symposia and conferences, and, as a consequence, there are now considerable opportunities for contact between those working within each of a number of limited fields. The main function of international congresses has become the complementary one of discussion between workers in different branches of broader fields. On this standard, the Ninth International Congress of Genetics, held this year in Bellagio during August 24–31, has been more successful than the two preceding ones (Edinburgh, 1939; Stockholm, 1948), and the organizing committee deserves the gratitude of all the members who participated.

The reasons for this success are essentially twofold. First, the number of participants—more than eight hundred—though somewhat larger than at the Eighth Congress, was still small enough for everyone to meet everyone else. With numbers exceeding, say, one thousand, personal contacts outside the sessions can only be selective and require deliberate planning. Second, the Congress was centred not on a town but on a small and quiet holiday resort. In Bellagio, members of the Congress were accommodated in hotels along a short stretch of the shore, and most of the cafés were in the same stretch: thus meeting, or looking for, any member outside session time was only a matter of walking a few yards. Unfortunately, Bellagio could not accommodate all the members: part were accommodated ten minutes away by boat across the lake, and the two groups became effectively separated in the evening.

The plenary sessions of the Congress were held in the dining-hall of a big hotel, with unsatisfactory acoustics and ventilation, and the sectional sessions were held in the classrooms of a local school, some of insufficient capacity. These shortcomings were the price to be paid for by choosing a locality without the facilities of a university, but it was well worth paying in view of the other advantages. There are two lessons which this Congress has brought home. One is that the main purpose of a congress can be achieved only if the numbers are kept well below the thousand mark. The other is that a small centre is preferable to a large town; if it could also have lecture-room facilities of university standard, then so much the better.

The work of the Congress was arranged in a novel way. The afternoons were reserved exclusively for plenary sessions, each with three or four invited papers—twenty-seven in all. During the mornings there were eight special sessions simultaneously for papers of fifteen minutes length (about three hundred in all). These special sessions were interspersed with invited lectures (fourteen in number), not overlapping with one another.

It would be impossible to give here more than an idea of trends in genetics, as detectable at the Congress.

The study of the part the genes play in the function of the cell, and secondarily in the organism, has become one of the central fields in genetics. This trend can be detected quite clearly even in indirect approaches: for example, researches on the arrangement of the genes along the chromosomes, on the induction of specific mutations, on the process of mutation itself, and even on quantitative inheritance, are all strongly biased towards this functional aspect. The opening address of the president, Prof. Richard Goldschmidt, on what he called the dynamic versus the static approach in genetics, put into a nutshell what became increasingly clear as the work of the Congress proceeded.

Another impression from the papers presented at the Congress is that the microscopic study of the chromosomes has reached an impasse, except as a branch of comparative morphology : it is waiting for substantially new techniques and substantially new ideas. As for the former, there was one demonstration on electron microscopy of chromosomes in meiosis which was of enough interest to suggest that this might be one of the new techniques.

The genus *Drosophila* has now come back into its own for a new purpose: the study of natural populations. Under the stimulus of genetic investigation so much work has been done on the systematics, the ecology, the comparative anatomy (including comparative karyology) of the innumerable species of *Drosophila* that this genus is now the ideal tool in this field.

The numerous papers presented showed that the interest in quantitative inheritance has expanded enormously since the last Congress. If its exponents can keep the distinction between statistical tools and biological ends clear, this is obviously a field of great future importance.

As to human genetics, there is a growing interest both in the study of inheritance of particular conditions and of the comparative genetics of populations. Indeed, man takes now a rank not far from that of *Drosophila* and of micro-organisms as a subject for genetic research.

The Congress will certainly give fruits both in the direction of personal friendship, renewed or promoted *de novo*, and of new ideas arising from cross-fertilization.

G. PONTECORVO

INDUSTRIAL RESEARCH DIRECTORS

THE report of the third Conference of Industrial Research Directors and Research Managers, organized by the Industrial Research Committee of the Federation of British Industries, which was held at Ashorne Hill during April 17–19, 1953, has now been published*. The main subject of the conference was the commercial utilization of research results, and the report thus deals with an aspect of productivity with which the Advisory Council on Scientific Policy and the Department of Scientific and Industrial Research are increasingly concerned. Dealing with the problem from the point of view of company management, Lord Baillieu, who outlined policy and practice in the Dunlop Rubber Co., urged that it is essential to operate within our resources of finance, man-power and equipment. Research programmes should be conceived and keenly reviewed in terms of the conditions which a new idea or discovery must meet to achieve success; but we should not lose sight of the wider horizons and fundamental researches which have challenged the ingenuity and courage of men, and to which the British genius has responded so outstandingly. From the production point of view, Mr. G. S. Samways thought that in the metal container industry science has opened the way to revolutionary rather than evolutionary changes; research presents a problem not in finding ideas or in the method of implementation, but in finding the right type of young men and the large capital investment required. From the research point of view, Dr. N. P. Inglis urged the importance of a full and harmonious relationship between research and production departments. Elimination of problems of understanding, communications, joint consultation, etc., is largely a matter of personnel, and particularly of securing the right personnel and moving them about in the right way in their early years. Mr. E. R. Davies, describing the relations between research work and production in Kodak, Ltd., emphasized the way in which collaboration between plant and research workers is fostered by frequent informal as well as formal contacts, though the manufacturing departments are not paralleled entirely by laboratory groups in the research department; the four main types of manufacturing activity have been kept successfully in touch with development work and research groups through a system of four senior co-ordinators. Mr. J. B. Mitford stated that in Fibreglass, Ltd., the production department looks to the research department for new manufacturing methods, or revolutionary improvements in existing methods, for the rapid tracing and elimination of causes of trouble in regular manufacture, and for the provision of a testing and advisory service on raw materials and finished products. Frequently, he admitted, the production side is at fault in failing to give the whole of the facts, and he stressed the necessity of research and development men establishing a high reputation with the junior management and production people at the foremen-level.

The papers on utilization of research results as a sales problem, whether from the sales or the research point of view, and the subsequent discussion indicated that it is not quite so easy to establish a satisfactory relation between research and sales departments as between research and production departments. The essential point seems to be to maintain a proper balance and relation in the traffic of ideas between the two departments, and it is desirable that the practical experience of the sales side should receive full consideration in any discussions on the shaping of research and the evaluation of research progress. There is a place for creative-minded scientists with commercial instincts in the sales organization, in order to digest the import of sales intelligence and translate it into research ideas; but Dr. H. E. Merritt pointed out that it is also essential that the product situation should be reviewed, past performance appraised and probable future trends analysed at a high level in management. Much discussion centred on the training of salesmen, though the need for technical training was also fully recognized.

The fourth session was concerned with creating the right atmosphere. This, Mr. H. C. H. Graves urged, is partly a matter of human relations, and he thought there is room for some research into administrative methods, etc., of improving co-operation. If the importance, integrity and dignity of the individual are recognized, group attitudes would adjust themselves satisfactorily: the important thing is to encourage the right overall attitude to the economic objectives of the firm and industry, and appreciation of the individual as a participant in a team working for a common end. Mr. H. W. G. Hignett maintained that the preservation of good relations between the research department and other departments depends mainly on mutual respect, which can be engendered in many ways, not all of them technical. From a purely technical point of view, Mr. Hignett urged that four maxims should be observed: never give advice until all relevant facts are known and the background is clearly understood; with this proviso, never fear to criticize when constructive criticism is in the company's interest; never relax efforts to make research reports concise and clear; and, wherever possible, let other departments take more than their fair share of the credit for exploiting the results of research. Finally, to secure full value from the research effort of Great Britain, we need a little more imagination and a lot more courage. Discussion centred on the importance of good organization, the danger of over-organization destroying personal initiative, and the need for making all workers aware of the dependence of our economic survival upon the development and exploitation of new research ideas. The right atmosphere can be created on the basis of mutual trust in one another and in each other's integrity and sincerity of purpose.

ATHLONE FELLOWSHIP SCHEME FOR CANADIAN ENGINEERS

THE Athlone Fellowship Scheme, now in its third year of operation, is designed to bring to Great Britain every year thirty-eight Canadian graduates in engineering for postgraduate studies extending over two years. The Fellowships are tenable in industry or in a university, or may be divided between both. They cover the cost of travel to and from the United Kingdom, with a subsistence allowance of £6 10*s*. a week, the cost of tuition at a university and allowance towards text-books, and a travel grant of £25 a year for journeys within the United Kingdom. The net cost of the scheme is carried by the British Government. Some account of the operation of the Scheme was given by Dr. W. Abbott in a paper read by him on April 10 at a joint meeting of the Institutions of Civil Engineers, Mechanical Engineers and Electrical Engineers.

There are two classes of award: one, for those about to graduate, on a quota basis, which ensures not fewer than two awards in each Canadian university (with the exception of New Brunswick); and, on a national basis, for those who have already graduated and are at work. The latter selection is at present experimental. The fundamental aim of the Scheme is to familiarize Canadian graduates with British industry, and it is thus desirable to ensure that as many as possible of the Fellows enter industry and saturate themselves with workshop techniques and the products thereof. Most graduates, however, have preferred to continue their studies in a university, with the view of securing a higher degree. This is due to the fact that North America is 'higher-degree conscious' to a much greater extent than is Great Britain, and research appointments in Canada invariably call for higher degrees, usually the doctorate. During 1952–53 eighteen of the Fellows opted for university training, and only nine for industrial training, as compared with twelve each, respectively, during 1951–52; and if this trend continues the basis of the Scheme may require re-examination.

The Scheme is best suited to the requirements of the graduates in mechanical, electrical and chemical engineering, the position in civil engineering being more difficult because much of the work of prime interest to Canadian engineers—for example, water conservation and irrigation schemes—lies overseas. Perhaps the most important single factor operating against the success of the Scheme is the intense demand for graduates from all branches of the engineering industry, both in Canada and the United States. Higher starting salaries, as much as 400 dollars a month, are offered, with attractive conditions. Only graduates able to take the long view are likely to offer themselves for Fellowships, and it is probable that the great bulk of the graduates with a practical bent do not apply for Fellowships but seize the opportunities now presented in Canada. So far as each individual is concerned, the success of the Scheme depends very largely on the people he meets during his training, and upon the people with whom he lives. Not all of these may be much concerned to send the young man home with a good opinion of Britain and its institutions.

CONTROL OF MULTI-RESISTANT HOUSEFLIES

By H. WICHMAND

Government Pest Infestation Laboratory, Springforbi, Denmark

AS the fly-populations on practically all Danish farms (owing to an excellent organization of the control) have developed resistance to the chlorinated hydrocarbons used as insecticides, in 1951 I examined the possibilities of safely using Parathion in fly control. Obviously it would be too dangerous to spray this substance on the walls of stables, pigsties, etc., and furthermore, the Parathion would be rapidly hydrolysed by the lime-wash with which all the stable walls in Denmark are covered.

So we looked for a cheap but still sufficiently strong material which might be impregnated with Parathion and used as strips suspended under the ceilings like festoons. In the United States, strips of metal screen treated with Dieldrin and other chlorinated hydrocarbons have been used for fly-control[1], but this material was too expensive for us, and we found gauze strips (as used for bandages) most suitable for the purpose. Laboratory investigations showed that gauze impregnated with a 2·5 per cent solution of 35 per cent Parathion had a rapid killing effect on houseflies, and that the gauze strips after suspension for two months in an air-conditioned room with a constant temperature of 25° C. and continuous air renewal still had the effect that, of flies transferred to cages covered by the strips, 96 per cent were paralysed within two hours, and 100 per cent within three hours. Then experiments were carried out in two stables seriously infested with flies. Approximately 1 m. of gauze was used for every square metre of ceiling, and after a few days the fly population had been reduced from a number of about two hundred per animal (cows, horses and pigs) to two or three per ten animals.

A report was published eventually in a Danish farmers' bulletin, and the pesticide industry began the production of fly-strips. The industrial strips were produced in a length of 10 or 100 m. and a breadth of 2·5 or 5 cm., and contained 0·5 or 0·7 gm. Parathion per strip of 10 cm. × 2·5 cm. (2 or 2·8 gm. per sq. m.). Flies exposed to newly made strips only needed a touch to receive a lethal dose. Strips which had been in use for six months in an air-conditioned room with a temperature of 20° C. and continuous air renewal killed 100 per cent of the flies after one minute's exposure.

In the summer of 1952 such strips were used in the stables, cowsheds, pigsties, etc., of about 20,000 farms. In the summer of 1953 the strips have been used on between 75,000 and 100,000 farms, to the satisfaction of nearly all the farmers.

The effect only failed in a few cases, particularly where the strips were only used on a single farm in a village; general use elminated the fly trouble until the end of the season.

The Danish Health Department has permitted the use of the method, and no accidents have been reported.

CULTIVATION OF POPLARS

THE wood of poplars has for long been used for making matches, but research work during the present century has shown that it is utilizable in other industries. Mr. T. R. Peace, of the Forestry Commission, describes the work on poplars in Bulletin No. 19 of the Commission*, a publication which supersedes Forest Bulletin No. 5 (1923) and Forestry Commission Leaflet No. 27 on "Poplar Planting" (1948). The chief attraction of the poplar as a tree crop is the rapidity of its growth, for on suitable sites it grows much faster than any other tree hardy in the British Isles; and there is a good market for its timber which, in addition to matches, is used for veneers and other purposes. Propagation, which is usually by cuttings, is easy, and planting and subsequent treatment are also not difficult. The troubles are that the choice of varieties is bewildering and becomes more so with the production of new hybrids; the selection of the site for raising the crop needs care and variations in propagation and tending.

The cradle for the growing of commercial poplars lies in Western Europe, and particularly in France, Belgium and the Netherlands. The main countries with large stands of natural poplar are Sweden, Finland, the United States and Canada. It is with the object of clarifying the central position of poplar propagation and planting that the present bulletin is written, and admirably illustrated. Mr. Peace points out that our knowledge of poplar cultivation and, in particular, of the growing of poplar in woodland or heavily grassed sites is still very far from complete. The traditional practices that have long been followed on the Continent of Europe are not necessarily the best, and in any case may not always be practicable under the conditions met with in Great Britain. The published literature on poplars is very large but is most strictly specialized; only in Holland and Germany are there text-books covering all aspects of poplar cultivation, and these are in the languages of the countries.

The increasing interest in poplar cultivation is evidenced by the number of countries which have formed national poplar commissions to promote the study of poplars and encourage their cultivation. On the initiation of the French, an International Poplar Commission was set up in 1945, holding its first meeting in Paris.

The French peasant in some parts of France has long known the poplar and the rapidity of its growth, and instances are known whereby when a daughter is born the father has planted a few rows of poplars on his land to form her *dot* when she is married.

The trees of chief interest are the white poplars, aspens, balsam poplars and black poplars. The bulletin deals with botanical description and choice of variety, sylviculture (site, nursery practice, and planting), diseases and pests (particularly insects and fungi), and properties and uses of poplar timber.

HELICAL STRUCTURE OF CRYSTALLINE DEOXYPENTOSE NUCLEIC ACID

By Dr. M. H. F. WILKINS

Medical Research Council Biophysics Research Unit, King's College, London

AND

Dr. W. E. SEEDS, Dr. A. R. STOKES and Dr. H. R. WILSON

Wheatstone Physics Laboratory, King's College, London

EXACT information about the molecular configuration of deoxypentose nucleic acid may well serve as the basis for understanding its biological function. It has been shown by X-ray diffraction[1,2] that molecules of deoxyribonucleic acid (in the form of sodium salt) exist probably in a helical configuration when in the paracrystalline state. Proof of the helical structure would be difficult to obtain from the two-dimensional view of the molecule provided by study of paracrystalline material. The regularity of the molecule is so great, however, that it may be crystallized in fibres[3,4] with a remarkably high degree of molecular order, and X-ray study[5,6] of oriented crystalline deoxyribonucleic acid has enabled a three-dimensional view of the geometry of the molecule to be obtained. The purpose of this article is to describe in a preliminary way further three-dimensional data of this kind and to suggest that proof is now available that deoxyribonucleic acid consists of two helical intertwined polynucleotide chains and to show, as a result of molecular model building, that this structure may be of the type suggested by Watson and Crick[7].

Franklin and Gosling[8] have recently published two- and three-dimensional Patterson diagrams of crystalline calf deoxyribonucleic acid, and by means of these arrived at conclusions in many ways similar to ours. The present work owes much to them and we wish to thank them for making available to us unpublished data. Further work is in progress; clearly all doubts about the basic geometry of deoxyribonucleic acid must be eliminated, for only then can the structural chemistry of its specific biological properties and the structure of nucleoprotein be approached on a sound basis.

The X-ray diffraction photograph of crystalline deoxyribonucleic acid (sodium salt) is shown in Fig. 1. In view of its very complex biological functions (for example, the genetical transforming[9] of bacteria) it is remarkable that its crystallinity is so perfect, for such crystallinity indicates a large element of molecular simplicity. We have found no difference in the diffraction patterns of crystalline deoxyribonucleic acid obtained from calf thymus, mouse sarcoma, human white blood cells, *E. coli*, pneumococcus and *Paracentrotus* sperm, although the ratio of bases in the deoxyribonucleic acids varies considerably with species. These facts, combined with the irregularity of sequence of nitrogen bases[10] and the hydrogen bonding between bases[11], produce a contradiction which is only resolved by a simplifying concept such as the specific pairing of bases suggested by Watson and Crick[7].

A qualitative view of the X-ray photograph shows several main features which point clearly to the type of structure involved, but the data may be interpreted with more certainty when the reflexions are indexed and intensities measured and plotted in reciprocal space. By using a high-resolution pinhole camera, about a hundred and twenty separate reflexions were resolved in the fibre photograph. Intensities were measured using a microdensitometer. The values are preliminary.

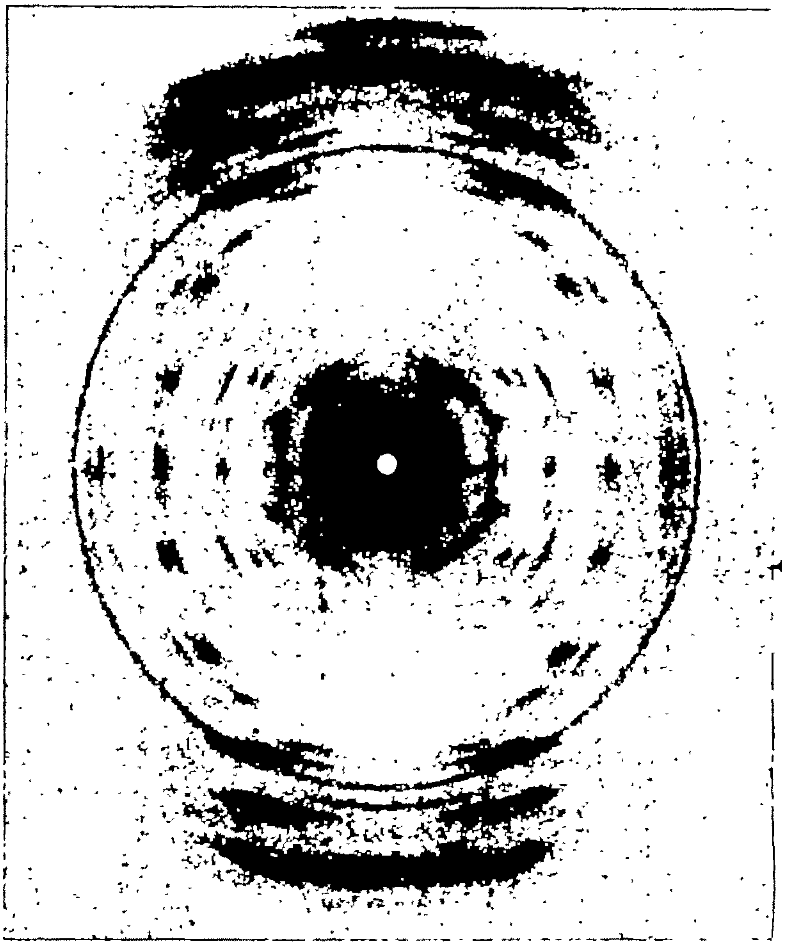

Fig. 1. X-ray diffraction photograph of a bundle of four fibres of crystalline mouse sarcoma deoxypentose nucleic acid (sodium salt) at approximately 75 per cent relative humidity. The ring is due to impurity. (Deoxypentose nucleic acid supplied by R. Barclay and L. D. Hamilton)

The unit cell of calf thymus deoxyribonucleic acid has been given[8] as face-centred monoclinic:

$a = 22 \cdot 0$ A. $b = 39 \cdot 8$ A. $c = 28 \cdot 1$ A. $\beta = 96\frac{1}{2}°$.

We find the values for mouse sarcoma deoxyribonucleic acid to be:

$a = 22 \cdot 2$ A. $b = 40 \cdot 4$ A. $c = 28 \cdot 1$ A. $\beta = 97 \cdot 1°$.

Deduction of the Main Features of the Structure

Fig. 2 shows a two-dimensional view of the intensities of reflexions plotted in reciprocal space. When reflexions overlap, the intensity is divided by the number of reciprocal lattice points possibly involved.

(*a*) *The structure is helical.* The pattern corresponds in striking fashion with the Fourier transform of a system of helices. The large empty trapezoidal space on and near the meridian strongly suggests a helix but could, however, also be given by alternative structures in which rods or sheets are inclined to the axis. These pseudo-helical structures can be distinguished, however, by the fact that they do not give several zeros of intensity on the layer lines, and the form function is not circularly symmetrical about the fibre axis. If paracrystalline deoxyribonucleic acid only were available, it would be impossible to establish the circular symmetry of the form function, and hence three-dimensional data obtained from study of the crystalline acid are necessary if the helical nature of the structure is to be proved. This is discussed later.

(*b*) *A major part of the helix has one sharply defined diameter.* The intensity distribution on the second layer line and on the outer parts of the equator alternates markedly between strong and weak and corresponds respectively with the functions J_2^2 and J_0^2 (squares of second- and zero-order Bessel functions). This diffraction would be produced by a helix of sharply defined diameter of about 18 A. The intensity on the 4th, 5th, 6th, 7th, 9th and 11th layer lines corresponds roughly to the main maxima of the functions J_7^2, J_6^2, J_5^2, J_4^2, J_3^2 and J_2^2 (Fig. 2), again for the same diameter of 18 A.

(*c*) *There are two coaxial* 18 *A. diameter helices spaced half a pitch-length apart.* The 1st and 3rd layer lines are weaker than the second, and the intensities correspond roughly with J_1^2 and J_3^2 (Fig. 2) respectively, for a helix of diameter approximately 10 A. The strong diffraction from 18 A. diameter helices observed on the 2nd layer line, but absent from 1st and 3rd, indicates that the structure contains two 18 A. diameter coaxial helices spaced apart along the fibre axis by about half the pitch-length of 28 A. (the layer line spacing) (see also ref. 8). The inner regions of the equator correspond to a smaller average diameter than 18 A., and if the 10 A. helix extends over a range of diameter from about 9 to 14 A. it will contribute mainly to the inner regions of the equator and will not affect much the outer region, which corresponds to J_0^2 of 18 A. The equatorial intensity distribution will then be accounted for by the addition of the amplitudes diffracted by the 18 and 10 A. helices (Fig. 2). The 18 A. diameter helices do not contribute J_4^2 to the 4th layer line; hence the thickness of the 18 A. helix in the axial direction must be at least 3·5 A.

(*d*) *Spaced centrally between the two 18 A. diameter helices is one helix of mean diameter about 10 A.* We expect that the 10 A. helix may contribute to the intensity of the 2nd layer line. If this intensity followed accurately a J_2^2 function, the heights of the maxima first and second closest to the centre of the layer line would be in the ratio 1 : 0·4. In fact, these heights are about equal. If a small amplitude of J_2, corresponding to 10 A. diameter, is added *out of phase* to the 18 A. J_2, such an effect would be produced (Fig. 2). Hence we expect the 10 A. diameter helix to be spaced along the helix axis *halfway* between the two 18 A. diameter helices, the whole system being coaxial. This 10 A. diameter helix is apparently that part of the structure which Franklin and Gosling have remarked[8] is not repeated 14 A. apart along the fibre axis. Indications of this single helix can, in fact, be seen on their two-dimensional Patterson diagram.

(*e*) *There are eleven nucleotides per turn of one helix.* This is deduced from the fact that there is a system of Bessel function maxima converging on the centre of the 11th layer line (see also ref. 8).

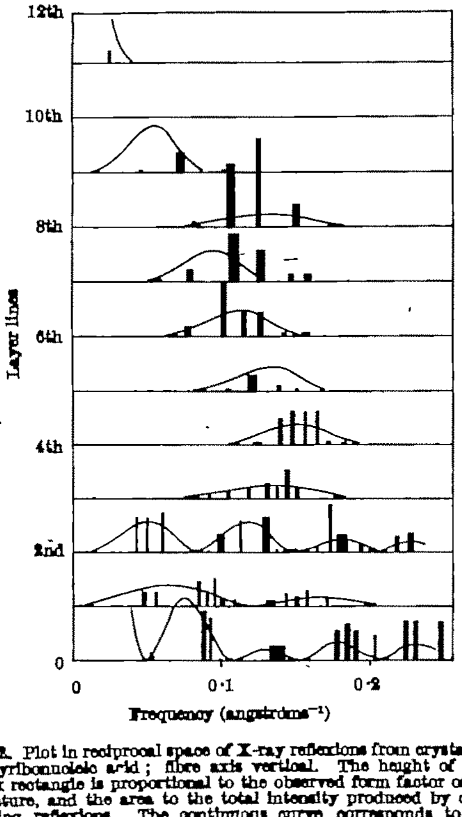

Fig. 2. Plot in reciprocal space of X-ray reflexions from crystalline deoxyribonucleic acid; fibre axis vertical. The height of each black rectangle is proportional to the observed form factor of the structure, and the area to the total intensity produced by overlapping reflexions. The continuous curve corresponds to the roughly calculated form factor for the helical structure suggested in the text

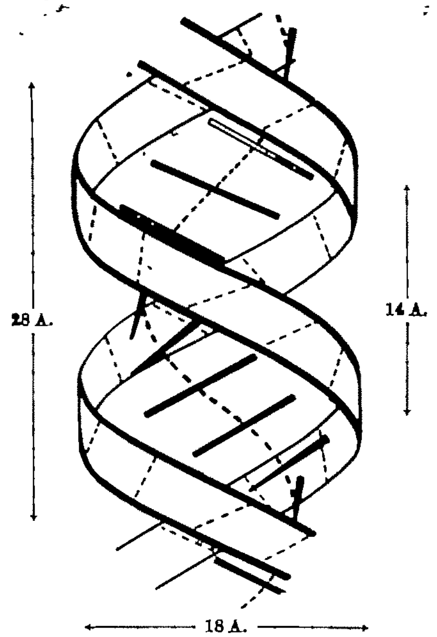

Fig. 3. The type of structure of the helical unit deduced from X-ray data of crystalline deoxyribonucleic acid. One helix of diameter approximately 10 A. is formed by a system of eleven inclined rods per turn of the helix. This helix is surrounded by two 18 A. diameter helices, each of which is also formed of eleven units per turn

(*f*) *The nucleotide shape resembles that of a rod inclined to the helix axis.* If the helical system is divided into nucleotides by planes at right angles to the helix axis, the intensities of the 10th, 9th and 8th layer lines would resemble that of the zero, 1st, 2nd and 3rd layer lines. In fact, this effect is observed in so far as the 18 A. diameter helix does contribute to the 9th layer line (though weakly) and is partly absent from the 10th. But it is anomalous that the 10 A. diameter helix does not contribute to the 10th layer line and the 18 A. helix does contribute, as J_4^2, to the 7th layer line. These effects would be explained if the nucleotides formed roughly a series of rods inclined at an angle of about 65° to the fibre axis in the opposite sense to the inclination of the helix. The X-rays are then reflected off these rods in a direction about 25° to the fibre axis. The 10 A. diameter helix, being in effect divided by inclined planes, diffracts very little energy along the meridian, and the 10th layer line is accordingly absent.

The structure of the helical system therefore begins to become clear and its probable form is shown diagrammatically in Fig. 3.

Circular Symmetry of the Form Function and the Elimination of Pseudo-Helical Structures

The fact that the form function, for example, on the 2nd layer line, alternates fairly smoothly between strong and very weak, indicates that it has circular symmetry about the fibre axis. Hence all pseudo-helical structures are eliminated. However, as the lattice is asymmetrical, a symmetrical form function is quite likely to produce general asymmetry of the intensity distribution. This effect, combined with some ambiguity of indexing, gave rise to the suggestion[8] that there might be a very definite asymmetry in the form function and therefore in the structure itself. If this were the case, the structure could not be helical unless the helix were considerably distorted. Probably the greatest asymmetry of reflected energy is observed on the 2nd layer plane. There is a marked tendency for the $h, k, \bar{l}$ points to fall near maxima of the J_2^2 form function and h, k, l points to fall near minima and, as a result, the energy is reflected asymmetrically. There is, however, little reason to suggest that the form function deviates much from circular symmetry, and this applies on all layer planes. There are, however, a number of real discrepancies, mainly in regions of low intensity, which probably result from slight distortions of the helix. In particular, it appears that the helix, when viewed along the fibre axis, may not be quite round in section but elliptical. The eleven-fold nature of the structure also produces some asymmetry of the form function, but reliable data on this are not yet available.

Water Content of the Crystals and the Number of Polynucleotide Chains in the Helical System

The water content of crystalline calf deoxyribonucleic acid has been given[10,11] as approximately 40 per cent of dry weight. We find a value of about 45 per cent for *E. coli* deoxyribonucleic acid. Together with density measurements[8], the water content may be used to obtain the number of nucleotides per repeat unit in the crystal and, hence, the number of polynucleotide chains in the helical system. Deoxyribonucleic acid is very readily denatured, and it would be unwise to ignore the possibility that its fibres contain an appreciable fraction of degraded material which may not produce a distinct X-ray diffraction pattern. It was assumed[8] that such amorphous material would have a higher water content than the crystalline. We find, however, that specimens of deoxyribonucleic acid which have been degraded always have a lower water content than undenatured material, and this content may be as low as 10 per cent (cf. ref. 12). Hence we expect that the number of nucleotides per repeat unit calculated from water-content measurements will, if anything, be greater than the true value. Our measurements indicate twenty-two or less nucleotides per turn of the helical system (using density 1·47 gm. per c.c.[8]). There appears to be no doubt that there are two and not three polynucleotide chains in the helical system, each chain having eleven nucleotides per turn of the helix.

Molecular Model Building

We have built molecular models of the type described by Watson and Crick[7] and have adjusted them to conform with our experimental data. The result is promising: it appears likely that in the paracrystalline state[1,3,7] the pairs of bases lie on straight lines passing through the helix axis and at right angles to it, and the C_4 and C_5 atoms of the sugar are in the staggered position relative to each other. In the crystalline state the planes of the bases (as suggested[7]) are inclined to the helix axis and the C_4 and C_5 atoms of the sugar are in the eclipse position relative to each other. The whole of the phosphate and sugar groups then lies approximately at the same distance 9 A. from the helix axis and forms two 18 A. diameter helices spaced about 14 A. apart along the helix axis. The pairs of bases resemble rods inclined at about 65° to the helix axis (see above) and form a single helix of diameter 5–13 A. halfway between the two 18 A. helices. The model as a whole corresponds closely with the structure deduced from X-ray data, and calculation of the diffraction pattern from the model is in progress. One objection to the structure might be that if eleven nucleotides are arranged on one turn of each helix, some of the interatomic distances between different atoms in the same phosphate-ester chain, for example, O—O, C—O, are less (about 2·7 A.) than usual Van der Waals distances. But as such small distances are found in peptide chains[13], this objection is probably not serious.

We wish to thank Prof. J. T. Randall for advice and encouragement; Dr. J. D. Watson and Mr. F. H. C. Crick, Miss R. E. Franklin, Mr. R. G. Gosling and Dr. G. L. Brown for discussion; Drs. L. D. Hamilton, R. Barclay, J. Rowen, H. Ephrussi, G. L. Brown and Prof. R. Signer for specimens, and Miss P. M. Cowan for advice on model building. One of us (H. R. W.) acknowledges award of a University of Wales Fellowship, and another (W. E. S.) a grant from the British Empire Cancer Campaign.

CORRELATION OF PLIOCENE AND PLEISTOCENE MARINE BEDS

By D. F. W. BADEN-POWELL
University Museum, Oxford

THE theory of glacial control, by which Pleistocene changes of sea-level are believed to reflect changes in the volume of the earth's ice-sheets, has been widely accepted; but it is not always realized that it depends on the idea that eustatic changes of sea-level have taken place, the proof of which depends on the accurate dating and correlation of raised beaches over great distances. This point was emphasized by Daly many years ago[1]. In particular, Deperet[2] tried to correlate some British raised beaches with the classical series in the Mediterranean, and I have made recently a fresh attempt, summarized here, to correlate British and Mediterranean marine beds, using the Mollusca as zonal fossils.

Ever since the time of Lyell, it has been realized that the earlier marine deposits of the Pliocene–Pleistocene series contain more extinct shells than the later beds, and Gignoux[3], among others, proved a gradual reduction in the extinct Mollusca of the Mediterranean area as the sequence is followed up from the Astian through the Calabrian to the Sicilian and Tyrrhenian beaches. In the British area, a similar progressive disappearance of extinct shells can be traced from the Coralline Crag through the Red Crag and the Icenian to the raised beaches and shell-beds of the Glacial Series, as is well known from the work of Wood[4], Harmer[5], Bell[6] and others.

This similarity between the two areas suggests a basis for general correlation, but it is difficult to equate the individual stages by this method alone.

In my own investigations I have found that the presence or absence of certain extinct species is important in subdividing the post-Icenian shell-beds of Britain, a point which I did not realize in my earliest work[7]. The oldest beds in the Drift are now known to contain such extinct forms as *Panopaea faujasii* and *Voluta lamberti* (in Norfolk and Aberdeenshire), species which are unknown in younger glacial beds. At a later glacial stage, a few extinct shells still survive, including *Nucula cobboldiae*, *Tellina obliqua*, *Purpura incrassata* and *Nassa reticosa*, as in the Corton Beds (East Anglia)[8], Yorkshire, Aberdeenshire, the Isle of Man, the Wexford Gravels of south-east Ireland and at Selsey (Sussex). In some of these areas the marine material is glacially transported, but its molluscan assemblage remains recognizable. In such 'late-glacial' beds as the Torbay and Portland raised beaches[9], the March Gravels (Fenland)[10], the Kelsey Hill Beds (Yorkshire), the Clyde Beds of Scotland and Ireland, and in much derived material in North Wales, Lancashire, Cheshire and Shropshire, the extinct shells have disappeared almost entirely. Finally, the still later Holocene beds of Scotland and Ireland contain no extinct species at all.

These facts were discovered by making as complete a catalogue as possible of all the species occurring in the Pliocene–Pleistocene series, and this investigation has also brought to light some very important facts about the past changes in the climatic belts as shown by the distribution of some of the fossils. Gignoux[3] and others have shown that the warm conditions of Astian time in the Mediterranean area gave place to increasing cold (with fluctuations) during the Calabrian and Sicilian, but that a warm fauna returned during the Tyrrhenian stage. Now it is most significant that an exactly similar climatic sequence is found in Britain, where the warm fauna of the Coralline Crag gave place to increasing cold during the Red and Icenian Crags, followed by a partial return of warm forms during the Corton stage[8] (in East Anglia, Yorkshire, Aberdeenshire, the Isle of Man, Wexford and Sussex). This climatic sequence, considered with the method based on extinctions, suggests the correlation shown in the accompanying table, the partial return to warm conditions in the Tyrrhenian and Cortonian being especially important.

Mediterranean	Britain
Holocene	Holocene
Monastirian	Portland raised beach, March Gravels, Clyde Beds, etc.
Tyrrhenian	Selsey Beds, Corton Beds, Wexford Gravel, etc.
Sicilian	Early Glacial, Cromer Till
(Erosion)	(Cromer Forest Bed)
Calabrian	Icenian Crag, Red Crag
Astian	Coralline Crag

It was found in practice that there are discrepancies in detail between the sequence in Britain and that in the Mediterranean; but these can be eliminated by assuming that the temperature gradient in the eastern Atlantic was steeper in Pliocene and Pleistocene times than it is to-day. This assumption helps to explain the mixture of warm and cold indicators found in the Crags and in the Calabrian, and also in some deposits investigated by me in Lewis[11] and in East Anglia[8]. This steeper temperature gradient would enable the cold 'Scandinavian' species and the warm 'Lusitanian' forms to live nearer together than they do to-day, and even to intermingle. This assumption also explains why it is possible to find mainly warm indicators in certain Mediterranean raised beaches, contemporaneous with a mixed warm and cold assemblage in England and chiefly cold indicators in the Scottish Clyde Beds, all dated as Monastirian.

These two methods of correlation based on extinction and on the reconstruction of the climatic belts of the past are strongly supported by a detailed study of the evolution of certain groups of Mollusca, and give the same correlations. For example, *Pecten islandicus* evolved from its Icenian ancestor at the same time that *Panopaea faujasii* was becoming extinct both in the Sicilian of the Mediterranean area and in the earliest glacial beds in Britain. An example of evolution within one group is seen in *Turritella*: *Turritella tricarinata* is common in the Astian and in the Coralline Crag, and evolved through Calabrian and Red Crag times into *Turritella communis*, which becomes the common form of this group at the close of the Calabrian – Red Crag stage. A comparison of certain Nassas of the two areas gives similar results: *Nassa pygmaea* seems to have evolved from *Nassa incrassata* during the Calabrian and Red Crag; and *Nassa reticulata* first appears in its modern form in the Tyrrhenian and Cortonian, having evolved from the Calabrian – Red Crag extinct species *Nassa musiva*. Several other shells, such as *Venus fasciata* and *Neptunea contraria*, show similar use in dating, but are not yet worked out in detail. These three methods based on extinction, climatic distribution and evolution agree in the correlation shown in the table.

It is hoped that the evidence for the correlations suggested here will soon be published in greater detail. They differ somewhat from those proposed recently by King and Oakley[12] and by Zeuner[13], but agree better with Lagaaij's conclusions based on the Bryozoa[14]. These marine horizons should prove useful in the future as a basis for correlating certain non-marine deposits (plant beds, fluviatile, volcanic and glacial), including some containing Palæolithic implements, and there is already good evidence to show that this will be a valuable outcome of this investigation.

There is also clear proof that the heights of at least the Tyrrhenian and Monastirian beaches (dated palæontologically) correspond well for Britain and the Mediterranean. So far as this evidence goes, it confirms the idea that eustatic changes of sea-level have really taken place, and therefore it helps to support one of the foundations of the glacial control theory: but it is most important to realize that the changes of climate reflected in the various marine fauna suggest that it is improbable that glacial control was the only, or even the most important, factor in determining changes of sea-level. Indolepyruvic Acid in Maize

THE several reports of the presence of indole acetaldehyde in plants (reviewed by Larsen[1]), coupled with the recent isolation of indoleacetonitrile from cabbage[2], suggest that numerous indole derivatives related to indole-acetic acid may be of natural occurrence. The importance of such substances as precursors or breakdown products of the natural auxin needs no elaboration. It was therefore thought worth while to make an extensive investigation of the indole derivatives occurring in plant materials.

For this purpose chromatographic methods have been developed with the view of their general applicability to the largest possible number of compounds. The solvent mixtures used by Jerchel and Müller[3], Wolf[4], and Yamaki and Nakamura[5], though suitable for the special separations studied by these workers, were not found applicable to the wide range of indole derivatives included in this study. Accordingly, a systematic investigation of different solvent mixtures was undertaken, comparing various common organic solvents, and leading to a more detailed study of the aliphatic alcohols and of the effect of the water content of the mixtures. The effects of *p*H were also studied, and ammoniacal conditions were adopted for separation of the acidic substances. These experiments led to the selection of *iso*propanol : 28 per cent aqueous ammonia : water in the ratio of 8 : 1 : 1 by volume as giving the best overall separation of the compounds. A similar choice of solvent has been reported by Bennet-Clark *et al.*[6] (cf. also Luckwill[7]).

The ascending technique with Whatman's No. 1 filter paper was used. The ionic compounds were found to give the best spots. For colour development, the following four reagents were found most generally suitable: the Salkowski and Ehrlich reagents, diazotized sulphanilic acid and diazotized *p*-nitroaniline. By selection of reagent and by taking advantage of the effects of *p*H, about thirty indole derivatives could be separated and identified. Of these, ten, including indole and skatole, tryptophane, tryptamine, hypaphorine, gramine, abrine, indole-acetic acid and its ethyl ester, and indoleacetonitrile, are known to occur in plants.

The method has been applied to the indole derivatives of maize endosperm (variety Country Gentleman). Extraction was by a modification of the method of Berger and Avery[8] but under conditions precluding bacterial attack, and minimizing oxidation of the extracts. It was found that along with indole-acetic acid there was present a second acid substance, of lower R_F, giving a pink colour with the Salkowski reagent. Both spots were prominent and distinctly separate. When the R_F of indole-acetic acid was 0·25, that of this second compound was 0·12. On extraction from the paper, this lower substance was found active in promoting the growth of *Avena* coleoptile sections and in causing curvature of slit pea stems. Comparison of the R_F and colour reactions with those of authentic samples (prepared by two methods[9,10]) identified this compound as indole-3-pyruvic acid. This has been previously shown to have auxin activity[11] but has not been demonstrated to occur in plants, although its occurrence as an intermediate between tryptophane and indole-acetic acid has been suggested (see ref. 1).

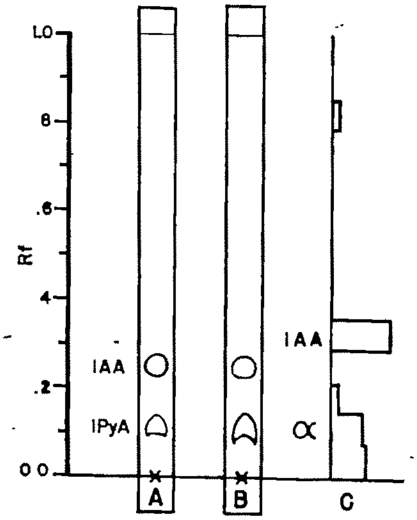

Fig. 1. *A*, Representation of the chromatogram obtained from synthetic samples of indole acetic acid (IAA) and indole-pyruvic acid (IPyA) and sprayed with the Salkowski reagent. *B*, Chromatogram of maize extract run under the same conditions. *X* is the origin in both cases. *C* is adapted from Bennet-Clark and Kefford's Fig. 1(*A*), ref. 12, where the bars represent the relative activity in coleoptile extension, above that of controls, of sections cut from chromatograms of etiolated broad bean shoot extract. Only those sections showing growth promotion are given here. The scale of the graph, and the solvent used, are essentially the same as in ours, but they employed the descending technique

Bioassays by Bennet-Clark[12], Lexander[13], and Terpstra[14] have indicated the presence in several plant extracts of an auxin having similar R_F values. This has been called accelerator α[12], substance a[13], and the IAA 'tail'[14]; but in the light of our experience, it seems likely that all of these refer to indole-3-pyruvic acid (see Fig. 1). Both the synthetic compound and that present in maize extracts break down under very mild conditions to yield some indole-acetic acid, which was readily identified on the chromatograms.

A detailed description of these experiments will be published elsewhere. One of us (B. B. S.) is working under a predoctoral fellowship in the biological sciences granted by the United States Atomic Energy Commission.

Promotion of Infection by Intravenously Administered Polysaccharides

A VARIETY of polysaccharides shows infection-promoting activity[1-4]. Nungester, Wolf and Jourdonais[1] noted that a crude gastric mucin preparation greatly lowered the minimum lethal dose of bacteria when the mucin together with the bacteria was given intraperitoneally, although it did not lower the minimum lethal dose sensibly when the mucin and the bacteria were given intravenously. This observation appears to be the basis of a belief that the infection-promoting activity is conditional upon the injection of the polysaccharide into a serous cavity[2]. The question whether a peritoneal infection can be promoted by a polysaccharide injected into the blood stream does not appear to have been examined critically. Since a number of polysaccharides are of interest as plasma volume expanders, this question might have clinical implications.

Infection-promoting potencies of dextran, levan, and mucin have been studied in mice given *Salmonella typhi*, 0·901, intraperitoneally. When mice (16–20 gm.) received intraperitoneally 0·1 minimum lethal dose of the bacteria, the mortality-rate was less than 5 per cent. When at the same time the mice also received 5 mgm. of native dextran or native levan, either intraperitoneally or intravenously, the infection was strongly promoted (mortality-rates greater than 70 per cent). Mucin, though similarly active when given intraperitoneally, was without activity when given intravenously. The peritoneum exudate was found to remain levan-free even after a massive dose (30 mgm.) of native levan had been injected intravenously.

It is evident from these results that the promotion of infection by the neutral bacterial polysaccharides given intravenously does not require the local enclosure of the bacteria in the peritoneal space by an envelope of viscous polysaccharide. Whereas the neutral polysaccharides given intravenously appear to exert their influence on an extravascular infection, it need not be postulated that the host-component inhibited by the polysaccharides is necessarily specifically extravascular. The levan failed to exert a decisive effect on intravenously inoculated bacteria. Hence it must fail to suppress at least one of the effective systemic anti-bacterial principles. As to dextran, Smith *et al.*[3] have shown that it is without anti-complementary activity. We have found that, like mucin, native levan is lacking in infection-promoting activity when it is administered into the peritoneum of a mouse which has received an irritant (namely, a sub-lethal dose of bacteria) intraperitoneally 15 hours previously. This suggests that levan does not suppress the phagocytic activity of leucocytes which have gathered in the peritoneum in the course of the inflammatory process. In the light of these observations, it is perhaps permissible to speculate that the neutral polysaccharides, native dextran and native levan, are promoters of infection in the normal mouse because they modify the inflammatory process, with the result that transport of an anti-bacterial agent into the peritoneal space is restricted[4-8].

Since infection-promoting activity is clearly undesirable in a clinical plasma-volume expander, it has been reassuring to find that acid hydrolysis leads to a rapid attenuation of the activity of both levan and dextran. Whereas the native levan and the native dextran with a molecular weight greater than 10^6 were both highly active as infection-promoters, the homologues with molecular weight in the range 10^4–10^5 recovered from a partial acid hydrolysate of levan or dextran manifested a negligible infection-promoting activity when given either intravenously or intraperitoneally.

The high potency of the neutral native bacterial polysaccharides (native levan, native dextran), their ready availability, adequate solubility, simple constitution, and homogeneous condition suggest that their use as promoters of infection in the place of the currently employed hog gastric mucin may offer worthwhile advantages. Since these neutral polysaccharides given intravenously are able to promote an extravascular infection, the latter is available in a form in which its responses to an antibiotic can be tested in the absence of an interfering viscous vehicle at the site of the infection. Furthermore, it may be anticipated that the range of action of the intravenously effective promoters will not be limited to peritoneally produced infections, but will also extend to infections produced at other vascularized sites.

Heteropycnosis in the Autosome Segments of *Ceriagrion coromandelianum* (Odonata)

THE sex-determining mechanism in dragon-flies consists, as a rule, of XO—XX chromosomes, and the X-chromosome in the spermatocyte divides equationally in the first, and passes undivided to one pole or the other in the second, meiotic division[1-4]. In this respect, the X-chromosome of the male germ-cell in the Odonata behaves as in the Heteroptera, in which group also it usually divides in the first meiotic division only. We find that the chromosomes of the damsel-fly, *Ceriagrion coromandelianum*, exhibit another important feature in respect of which they resemble the hemipteran chromosomes; that feature is the presence of Feulgen-positive interconnecting threads joining the chromosomes at the spermatogonial metaphase, and also at the first and second meiotic metaphase. Such interconnecting chromatic threads are known to exist in many hemipterans[5-8]. Associated with the presence of these threads is a high degree of heteropycnosis of autosome segments. At pachytene the paired chromosomes carry deeply stained, condensed knobs. These heterochromatic segments occur in all chromosome pairs. The interconnecting threads, in our opinion, are derived from the chromosome matrix. It is well known that the protein framework of the heterochromatic chromosomes (or chromosome segments) differs from that of euchromatic chromosomes[9]. It is likely that the nucleoprotein matrix synthesized by these segments is cohesive[7] and that any fortuitous contact and subsequent separation between chromosomes result in the drawing out of the matrix substance into fine threads.

Another point of resemblance between the chromosomes of Odonata and Hemiptera might be considered to have been furnished by the discovery, apparently, of *m*-chromosomes in several dragon-flies[1,3,4]. These elements have been held to correspond to the *m*-chromosomes of Coreidæ (Hemiptera). Our own observation of the chromosomes of *C. coromandelianum* has, however, convinced us that there is scarcely any justification for naming the smallest pair of chromosomes of this organism as *m*-chromosomes, as Chaudhuri and Gupta[4] have done. The *m*-chromosomes of Coreidæ are characterized by non-association during meiotic prophase, whereas the smallest chromosome pair of *C. coromandelianum* pair regularly. The so-called *m*-chromosomes, like the other elements, in this organism are found completely paired during pachytene; at diplotene and diakinesis also they are not distinguishable from the others in this respect. It seems, therefore, preferable not to name the small chromosomes of *C. coromandelianum* as *m*-chromosomes. As White[10] holds, this term should be applied to chromosomes showing the anomalous behaviour characteristic of the *m*-chromosomes of Coreidæ—a condition not fulfilled by any chromosomes in the Odonata.

Regular Occurrence of the Haploid Number of Chromosomes in Mesenchymal Cells of the Tail Tip of *Rana pipiens* Tadpoles

The recent report by Lindahl[1] that the micromeres in certain sea urchins give rise to cells which contain the haploid number of chromosomes has far-reaching implications. Since the mesenchymal cells are the principal derivatives of the micromeres, it now seems pertinent to examine the chromosome numbers in such cells in animals of different groups.

In whole mounts of tail tips from normal tadpoles of *Rana pipiens*, a conspicuous feature is the discrepancy in size between the cells and nuclei of the epithelial covering and those of the connective tissue. Camera lucida projections of nuclei in the two layers give areas for the mesenchyme nuclei one-half those of epidermal nuclei (ratio 0·45 ± 0·08). The depths of the nuclei as measured by focusing are about the same, thus giving a twofold difference in nuclear volume.

Table 1. Numbers of Cells with Given Numbers of Chromosomes

Type of cell	Numbers of chromosomes				
	26	21–25	13	10–12	>13
Epidermal	10	6	—	—	—
Mesenchymal	—	—	21	13	3

A preliminary survey of the literature does not reveal any chromosome counts in these tissues. This is not surprising, since the mitotic figures, after the standard methods of fixation, are difficult to analyse. The chromosomes are small and usually closely packed. For the present study, in addition to tail tips fixed within a minute or two after cutting, tips were at hand which, following a suggestion of Fankhauser[2], had been allowed to stand in spring water for 30–60 min. prior to fixation. By this treatment the chromosomes are spread apart in a manner similar to that recently described by Hsu[3] for human cells in tissue culture. In epidermal cells in the tips of treated tails, the chromosomes at metaphase are beautifully separated in a flat plate. In mesenchymal cells, the majority of figures resemble pro-metaphases, with chromosomes sufficiently discrete to allow counting by careful focusing. The use of whole mounts makes possible the analysis of intact cells the position of which has not been disturbed. The tips were fixed in Smith's formalin-dichromate-acetic mixture, stained with Galligher's hæmatoxylin and fast green and mounted whole in 'Clarite'.

The results of the counts for epidermal and mesenchymal nuclei are given in Table 1. From tadpoles of three clutches, nine normal and six regenerating tips were examined, the latter because of their abundant mitoses. It was possible to count a few figures in tips that were not treated with spring water. No differences in chromosome numbers were found in treated and untreated tips. Sample divisions in epidermal cells of each tip showed exactly 26 chromosomes in most instances—that is, the diploid number for *Rana pipiens* (Briggs[4]). In mesenchymal cells, 21 out of 37 mitoses showed exactly 13 chromosomes, while less clear cases gave 10–12. A few anaphase and telophase figures contained 13 chromosomes in each daughter group. Areas of these mitoses drawn with the camera lucida were about one-half those of the comparable epidermal divisions. Endothelial cells and chromatophores gave some counts that were close to 13 and others that were higher but could not be seen to be 26.

Nuclei with two nucleoli are not uncommon among the mesenchymal cells. These nuclei are larger than the average. Sometimes a single cell contains two nuclei, each with a single nucleolus. Whether there is occasional restoration of the diploid condition or whether the diploid state only precedes the haploid is not yet clear. In one mesenchymal cell with more than 13 chromosomes, homologues lay noticeably paired. This may represent either a precursor of, or a sequel to, a reduction division.

Whether the haploid chromosome complement appears in cells of mesodermal origin in other organs in the frog remains to be determined. Parmenter[5] reports the diploid number in cells of the peritoneum. The frequent occurrence of 13 chromosomes in mesenchymal cells in the tail of *Rana pipiens* suggests the possibility of a somatic reduction in chromosome number at some earlier stage in development, at least in the tail. It is hoped that further analysis will show at what time this form of nuclear differentiation takes place.

Listeria Infection in the Guinea Pig caused by Feeding with Aureomycin

The toxicity of aureomycin to guinea pigs, reported earlier by one of us[1], has been further investigated, a part of the results having been published elsewhere[2]. Since it was found that aureomycin is far more toxic to guinea pigs when administered orally than by subcutaneous injection, it was concluded that this specific action of the drug must be primarily connected with the processes taking place in the digestive tract. Attention was therefore directed to the changes in the composition of the intestinal flora arising from the oral administration of aureomycin.

Cæcal samples of the animals were inoculated in different media and the types of micro-organisms found in the largest numbers were isolated. Distinct differences in the cæcal flora between the aureomycin group and the control group could be established as early as 24 hr. after the beginning of the experiments. A striking feature in the aureomycin group was the abundance of an organism belonging to the family Corynebacteriaceæ, genus *Listeria* (*Listerella*). The same bacteria, together with anaerobic sarcina (cf. ref. 3) and aerobic, spore-forming rods, were found by direct microscopic examination to dominate in the cæcal samples of aureomycin-animals. Cells of *Oscillospira*, *Fusobacterium*, *Spirochaeta*[4] and *Borrelia*, abundantly present in the control animals, had almost disappeared in the aureomycin-fed animals, and the number of lactobacilli and yeasts was greatly reduced.

Testing *in vitro* the activity of different antibiotics on the isolated cultures of *Listeria* showed that the organism tolerates rather high concentrations of aureomycin but is more susceptible to penicillin and chloromycetin. Accordingly, it should be possible to prevent or cure the toxic effects of aureomycin by administration of penicillin or chloromycetin. Experiments showed that this could indeed be done. Most of the guinea pigs which had been kept on a diet containing penicillin or chloromycetin previous to the feeding of aureomycin did not develop symptoms of toxicity at all or showed them only transiently. In some cases it was also possible to stop the loss of weight and cure the 'disease' already started by oral administration of penicillin or chloromycetin, or to prevent the development of the disease by administering penicillin or chloromycetin simultaneously with aureomycin right from the beginning of the experiment[2].

The toxic symptoms in the aureomycin-fed animals included a distended belly, pale-grey focal necroses in the liver, and red infarcts in the lungs. These symptoms are in good agreement with those given in the literature[5] for *Listeria* infection. Similar changes leading to death in one week developed when healthy animals were injected intraperitoneally with the isolated *Listeria* cultures. The spleen, however, which in the aureomycin-fed animals had decreased in size and was of a pale pink colour, was in this case large and dark purple, an observation made earlier with rabbits injected with *Listeria* cultures[5].

The results obtained indicate that the toxicity of aureomycin for guinea pigs is evidently due to an unfavourable change in the intestinal flora. By suppressing certain strains of bacteria, aureomycin permits the active growth of other organisms which normally play only a subordinate part in the intestinal flora. One of these bacteria, *Listeria*, is harmful to the guinea pig, causing typical symptoms of toxicity and leading in most cases to the death of the animal.

Fertilizing Capacity of Frozen Human Spermatozoa

Montegazza[1] observed the survival of human spermatozoa after exposure to a temperature of – 15° C. He speculated that in the future, frozen semen might be used in animal husbandry and even proposed that a man dying on the battlefield might, by his wife, beget a legitimate child after his own death. Other workers[2] have reported the survival of human spermatozoa; however, it was not until Polge, Smith and Parkes[3] reported increased survival of frozen human spermatozoa employing glycerol as a protective agent that practical application seemed possible. Work in our laboratory[4], recently, indicated that treatment with 10 per cent glycerol prior to freezing with 'dry ice' produced an average 67 per cent survival of human spermatozoa obtained from five young healthy men.

Parkes[5] has succinctly stated the problem of the frozen-thawed human spermatozoon: "A much more important and doubtful point is whether vitrification affects the power of the spermatozoon to fertilize and activate the egg and induce normal embryonic development". The following observations have been made on fertilization and activation of the egg.

Three recipients have been successfully inseminated with frozen semen: one woman, nulliparous, has missed six menstrual periods, has cervical softening and uterine enlargement, and has developed other presumptive signs of pregnancy. The second woman, primiparous, has subjective signs of pregnancy, and one week after her first missed menses the Aschheim – Zondek test was suggestive; following an additional seven days of observation the test became positive. Five menses have not occurred. An X-ray film shows a normal developing fœtal skeleton. The third recipient, nulliparous, has missed three menses and the Aschheim–Zondek test is positive.

The personal histories of the three recipients indicate a high degree of integrity and the source of the conceptions is valid.

The ability of glycerol-treated, frozen and thawed human spermatozoon to fertilize and actuate the human ovum has been observed. General clinical application of this fact must wait until normal embryonic development has been observed and the progeny are declared normal.

We wish to thank Drs. W. C. Keettel and J. T. Bradbury, of the Department of Obstetrics and Gynecology, for their co-operation and encouragement.

Thoracic Glands of *Iphita limbata* Stal.

The thoracic gland has been shown in a number of insects to be the immediate source of the moulting hormone. It has been demonstrated recently that the neurosecretory cells of the brain activate the thoracic gland and thus bring about moulting.

The thoracic glands in a number of insect groups still await discovery. Scharrer[1] suggests that the 'tracheal organs' in *Nepa* probably represent the thoracic glands; Williams[2] cites the presence of thoracic glands in *Oncopeltis*. Wigglesworth[3] describes in detail the thoracic gland in *Rhodnius*, which is the only complete account of the glands in the Hemiptera; he also points out that the 'tracheal organs' in *Nepa* reach their full development in the adult, while separate thoracic glands are present in nymphal instars which disappear in the adult. Prof. Wigglesworth (*in litt.*) informs me that a comparative study of thoracic glands in Hemiptera is being done in his Department by Mr. M. J. Wells.

In *Iphita limbata* Stal. (Pyrhocoridæ: Hemiptera) the thoracic glands have been found in the last two nymphal instars as well-defined structures, associated with the inner lobe of the thoracic fat body. The gland on each side consists of a loose collection of large cells with conspicuous chromatin and secretion product, lying along the periphery of the inner lobe of the fat body, which is well tracheated. Under the ordinary microscope they are not visible unless stained, but they could easily be seen and studied under the phase-contrast microscope. Fig. 1 shows the cells of the gland under the phase-contrast microscope. These cells remain more or less in contact and show an irregular shape and lobed nuclei. They appear yellowish under the phase-contrast optical system.

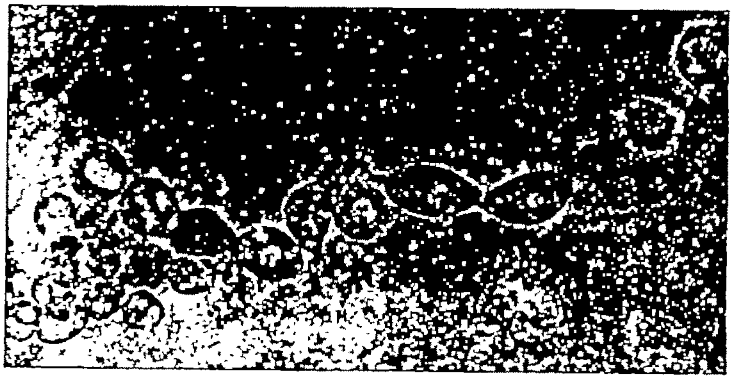

Fig. 1

The study of the structure and physiology of these cells is being continued.

Biogenesis of Nicotine

Following the demonstration that the amino-acid tryptophane can readily be converted by barley plants into the alkaloid gramine[1], the study of the biogenesis of alkaloids carried on here has included investigations into the possibility that nicotine may arise from tryptophane in a manner similar to the formation of nicotinic acid in animals and micro-organisms[2]. Recent discussions of this possibility[3,4] prompt me to describe part of these investigations.

DL-Tryptophan, containing carbon-14 in the β-position, was fed, in the form of its acetate, to young tobacco plants *via* the roots. The leaves, which became radioactive, were dried, digested with 40 per cent sodium hydroxide solution, steam-distilled and the volatile bases isolated as hydrochlorides. By chromatography on Whatman No. 1 paper using *n*-butanol/hydrochloric acid[5] as a solvent and developing upwards, the nicotine from the plant was separated from other products, its position (R_F 0·2 at 20°) being located by the bismuth nitrate/potassium iodide reagent[5].

The nicotine spots so obtained were found to exhibit no radioactivity measurable by a thin-window counter. The results so far obtained lend no support to the theory that the tryptophane molecule *in toto* is converted into nicotine, although the possibility that the pyridine ring is formed from the indole moiety is not excluded. Further investigations into the problem are in progress.

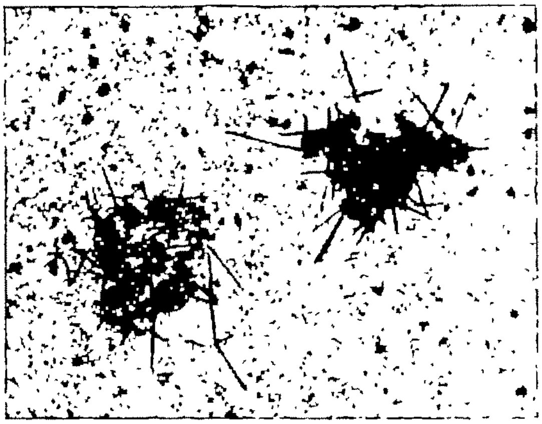
Tissue Dosage from Thorotrast in the Body

During the past twenty-five years a large number of people have been injected with thorotrast for radiographic purposes. Thorotrast is a colloidal solution of thorium oxide which, after injection, is rapidly taken up by the reticulo-endothelial system, particularly the liver and spleen, where the thorium remains practically indefinitely, and only some of its products may be excreted. In the course of time the action of the radiations may give rise to certain clinical symptoms[1], and this fact offers an opportunity for studying the correlation between the clinical effects of radiations and the dosage delivered to tissue. The amount of thorotrast in the given organ is often estimated from a measurement of the γ-ray activity, mainly due to thorium-C″, observed with a Geiger–Muller or scintillation counter[2]. Since, however, more than 90 per cent of the total energy dissipated in tissue is carried by the α-particles, which have a very short range, it is clear that a quantitative study of the radiation dosage requires a technique employing microscopic analysis. Furthermore, it is known[3] that thorotrast in the body forms aggregates of size similar to, or even greater than, the range of the α-particles; some of the energy of the α-particles is thus absorbed in the thorotrast itself, and in order to determine the energy dissipated in tissue this self-absorption has to be taken into account.

We have studied this problem by using the technique of α-track autoradiography. Histological sections, 3–10 μ thick, from organs containing thorotrast were obtained and used to prepare autoradiographs by means of Ilford *C.2* nuclear emulsions. Two methods were employed: in one, liquid emulsion was used; it was poured on to the mounted sections to a thickness of 50–100 μ and then dried quickly. In the second method, *C.2* plates were placed directly in contact with the sections and exposed under light pressure to ensure intimate contact. After the required period of exposure the sections were processed in the usual way and the α-particles observed through a microscope.

In order to calculate the tissue dosage it is necessary to determine the radioactive content of the section, that is, the activity of thorium and of each of its α-emitting products contained per unit volume of tissue. If the section were infinitely thin the various radioactive substances could be easily identified by the length of the α-particle tracks in the emulsion. With a section of finite thickness the length of track observed in the emulsion is shorter than the true range; even a single radioactive isotope in the section gives a continuous distribution of track lengths, from zero to the full range. The shape of this distribution curve can, however, easily be calculated. The measurement of the lengths of the tracks from a given area of the section thus makes it possible to determine the radioactive content of the section. Furthermore, by comparing the relative amounts of radiothorium and thorium in the section with those in the thorotrast itself, it is possible to deduce what the radioactive content was in the organ *in vivo*.

The next quantity necessary for the determination of tissue dosage is the fraction of the total energy of the α-particles dissipated outside the aggregates from which they were emitted. This can be calculated from a measurement of the areas of the aggregates in the sections by means of a square eye-piece graticule. The thorotrast shows up as yellow granular deposits against the blue-stained cell nuclei; the accompanying photomicrograph shows the appearance of some large aggregates, together with α-particle tracks recorded in the emulsion. From the observed distribution of aggregate sizes it is possible to calculate the fraction of the total energy, F, from all α-emitting substances, dissipated in tissue.



Photomicrograph of liver section showing large thorotrast aggregates with α-particle tracks

The average tissue dosage is given by the expression $D = NF\bar{E}$, where N is the total activity of the organ, that is, the total number of disintegrations per unit time, per unit volume of tissue, and $\bar{E}$ is the 'effective energy' of the α-particles, which is related to the radioactive content of the organ.

The accompanying table gives an example of the results of such calculations of tissue dosage. All figures refer to one patient, who was given an injection of 22 ml. of thorotrast in 1938. A splenectomy was performed in 1949 and biopsy samples from several other organs were taken at the same time; the autoradiographs were prepared in 1951.

Tissue Dosage to Various Organs

Section	Disintegrations per min. per mm.³ of tissue N	Percentage of energy dissipated in tissue F	Effective energy of α-particles $\bar{E}$ (MeV.)	Energy dissipated in tissue per min. per mm.³ of tissue D (MeV.)	Tissue dosage (rep. per week)
Spleen (interior portion)	260	1·8	5·33	24·9	4·8
Spleen (exterior portion)	28·2	26·5	5·68	42·5	8·3
Hilum of spleen	12·3	29·2	5·05	18·1	3·5
Liver	12·8	56·3	5·80	41·8	8·1
Lymph-node	1·45	81·0	5·33	6·2	1·2
Tonsil	0·49	66·6	5·88	1·9	0·4

The figures in the last column of the table give the tissue dosage in rep. per week. In the organs which took up most of the thorotrast, the spleen and liver, the tissue dosage was of the order of 8 rep. per week. Assuming a relative biological efficiency of 20 for α-particles[4], this corresponds to about 160 röntgens of X-rays per week. The accepted value of the tolerance dose for whole-body irradiation is 0·3 r. per week[4].

If all the products of thorium remained in the organ and if the thorotrast were mixed homogeneously with tissue, the tissue dosage to the spleen of the patient referred to in the table would be expected to be about 40 rep. per week. The greatly reduced dosage-rate actually observed is partly due to an escape of some products from the organs but mostly to the formation of the aggregates with the resulting self-absorption of the α-particles. As a consequence of this absorption the tissue dosage is not proportional to the concentration of thorotrast in the organ. This can be seen clearly when comparing the values in columns 2 and 6 of the table. While the total activity of the various organs, which roughly corresponds to the amount of thorotrast in them, varies by a factor of 500, the tissue dosage delivered to these organs varies only by a factor of about 20. The process in the body which produces the aggregates, probably of a physico-chemical nature, acts thus as a kind of compensating mechanism which results in a reduction of the radiation delivered to tissue.

The tissue dosage shown in the table represents average values for the given organ. Actually, within each organ the dosage is distributed non-uniformly. In most organs the distribution of the thorotrast aggregates shows the presence of a large number of small aggregates, of radii about 5 μ, and a very small number of large aggregates. These few large aggregates contain a considerable proportion of the thorotrast in the organ, and despite the self-absorption they produce a very intense tissue dosage in their immediate neighbourhood. On the other hand, the numerous small aggregates produce a uniform dosage to the whole organ, which is several times lower than the average value. The dosage delivered to tissue consists, therefore, of a uniform radiation of the order of 0·3–0·8 rep. per week, with a few hot spots in which the dosage may be fifty or even a hundred times higher. The significance of these results on the occurrence of clinical symptoms of radiation damage has yet to be established.

Our thanks are due to Dr. O. M. Henriques, director of the Finsen Laboratory, Copenhagen, for sending us the sections, and to the Medical Research Council for a grant which enabled this work to be carried out.

Origin of the Absorption Band at 1,550 cm.$^{-1}$ in Proteins

The infra-red spectra of proteins and polypeptides show strong absorption bands around 1,650 cm.$^{-1}$ and 1,550 cm.$^{-1}$ related to the peptide group. The 1,650 cm.$^{-1}$ band has been associated with the C=O stretching motions and the 1,550 cm.$^{-1}$ band has been assumed by some investigators to be an N—H deformation frequency of the monosubstituted amide (peptide) group[1]. Examination of dried, deuterated films of proteins has shown that the 1,550 cm.$^{-1}$ band shifts to 1,450 cm.$^{-1}$, but there still remains considerable absorption in the 1,550 cm.$^{-1}$ region[2].

We have examined solutions of proteins in heavy water in a double-beam infra-red spectrometer, compensated by placing in the reference beam an equivalent thickness of solvent, and at their isoelectric points we have observed the presence of two bands at 1,575 cm.$^{-1}$ and 1,550 cm.$^{-1}$ as well as the previously known 1,450 cm.$^{-1}$ band associated with deuterated peptides (see Fig. 1). In general, the 1,575 cm.$^{-1}$ band cannot be seen in the infra-red spectra of non-deuterated proteins because of the overlapping strong absorption[3] at 1,550 cm.$^{-1}$. The absorption band at 1,575 cm.$^{-1}$ is present in alkaline heavy water solutions of proteins and disappears in acidic solutions, but upon bringing such solutions to pH 9–10 the band reappears. The same behaviour is observed in a weak band near 1,400 cm.$^{-1}$, previously shown to be associated with ionized carboxyl groups in amino-acids and peptides[4,5]. These experiments in heavy water solutions thus reveal the presence of a 1,575 cm.$^{-1}$ band in proteins which, like the 1,400 cm.$^{-1}$ band, may be correlated with $COO^{\ominus}$ groups.

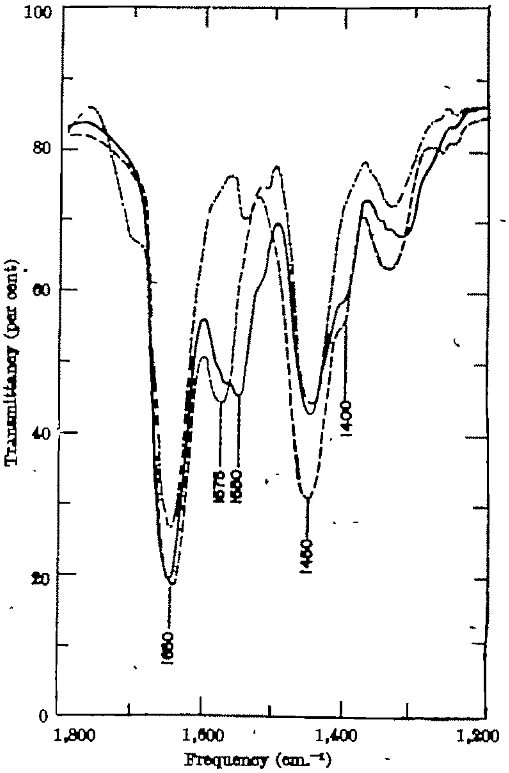

Fig. 1. Infra-red spectra of 10 per cent solutions of crystalline bovine plasma albumin in heavy water at various pH values: ———, at pH 6; – – – –, spectrum obtained upon bringing pH 6 solution to pH 9; — — —, spectrum obtained upon bringing pH 6 solution to pH 3

On the other hand, the band at 1,550 cm.$^{-1}$ remains upon acidification of heavy water solutions of proteins (which had been previously adjusted to the isoelectric point), but disappears in alkaline solutions. However, this change is irreversible; the 1,550 cm.$^{-1}$ band does not reappear upon acidification of alkaline heavy water solutions of proteins. Furthermore, if a heavy-water solution of plasma albumin, gamma globulin, or egg albumin at the isoelectric point is heated at 100° C. for two minutes, this 1,550 cm.$^{-1}$ band disappears. Judged by this behaviour, and since it lies at the same frequency as an original non-deuterated peptide absorption, this band may be associated with the peptide group as a whole, or a part of it which does not readily exchange its hydrogen with heavy water in the native state at its isoelectric point or in acidic solutions, but which readily exchanges its hydrogen in alkaline media or during the changes of structure accompanying heat denaturation.

Thus from the infra-red spectra of proteins in heavy water solutions at various pH's, we can conclude that the protein absorption band noted in the region of 1,550 cm.$^{-1}$ is a complex absorption band associated in part with —COO$^{\ominus}$ groups (at 1,575 cm.$^{-1}$) and in part with two kinds of peptide linkages: one type of peptide grouping is easily deuterated at room temperature, the other type of peptide group being deuterated at elevated temperatures or in alkaline solutions.

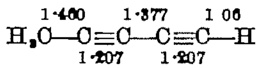
Microwave Spectrum of Penta-1 : 3-diyne

THE preparation of penta-1 : 3-diyne was reported by Armitage, Jones and Whiting[1], and it has recently been emphasized[2] that chemical and ultra-violet spectroscopic evidence supports strongly the attributed structure. In confirmation, we have measured the microwave pure rotation spectrum of the substance made by this method, as observed in a video sweep spectrometer, and find it to be that of a symmetric-top molecule of structure $H_3C—C\equiv C—C\equiv C—H$, all five carbon atoms lying on the molecular axis.

Measurements have been made on the $J = 4 \rightarrow 5$, $5 \rightarrow 6$, $7 \rightarrow 8$ and $8 \rightarrow 9$ transitions, in all of which the expected K-splitting is well resolved. The spectroscopic constant B_0 is 2,035·73$_8$ Mc./s., and the distortion coefficient D_{JK} is 20·0 kc./s. The distortion coefficient D_J is very small, not more than 0·2 kc./s. Lines due to molecules in excited bending vibrational states are also observed and show the characteristic type of pattern predicted theoretically[3] and found for similar molecules[4,5]. Measurements on the fine structures are being extended, and will be given in a fuller report later.

The moment of inertia, I_B, derived from B_0, is $412{\cdot}09 \times 10^{-40}$ gm./cm.^{2}, in good agreement with the most probable interatomic distances. Thus the structure



$$H_3C\overset{1\cdot460}{—}C\underset{1\cdot207}{\equiv}C\overset{1\cdot377}{—}C\underset{1\cdot207}{\equiv}C\overset{1\ 06}{—}H$$

(lengths in A.), with a tetrahedral methyl group in which d_{CH} is 1·10 A., is in accord with I_B. These bond-lengths are all close to values found for analogous bonds in related molecules, that for the central 'single' C—C bond being close to the 1·375 A. found for similar bonds in dimethyl triacetylene by Jeffrey and Rollett[6]. The spectrum is reasonably intense, showing that penta-1 : 3-diyne, like methyl acetylene, is unusual among hydrocarbons in having an appreciable electric dipole moment. We expect to detect spectra of H_3CCCCD, and it seems reasonably probable that lines due to molecules containing carbon-13 will be detected in a Stark modulation spectrometer now available, and so permit evaluation of a considerable part of the molecular structure.

We are indebted to Prof. E. R. H. Jones and Dr. M. C. Whiting for the gift of a sample of 1 : 4-dichlorobut-2-yne, from which the penta-1 : 3-diyne was made. This work was carried out in collaboration with the Physics Department of the Telecommunications Research Establishment, Malvern, and made possible by the loan of microwave equipment from that Establishment.

A New Isomer of Chlorogenic Acid from Peaches

NEOCHLOROGENIC acid, a new isomer of chlorogenic acid[1], has been isolated from Elberta and Halford peaches by the use of counter-current distribution. It differs from the isochlorogenic acid[2] isolated from coffee and it may be readily separated from chlorogenic acid which is present in somewhat larger amounts. Chlorogenic acid has been found in pears and apples[3] and its presence indicated in peaches[4].

An aqueous solution, freed of lipids, prepared from a water-saturated butanol extract of lyophilized peach *purée* was subjected to a 100-tube counter-current distribution[5] using the solvent pair ethyl acetate and 2*M* phosphate, pH 3·0. Analysis of the phenolic content of the tubes with Folin–Denis reagent[6] showed the presence of four bands. The first, $K \sim 0{\cdot}05$, consists of anthocyanins, polymeric and unknown materials. The second, $K = 0{\cdot}39$, is neochlorogenic acid. The third, $K = 1{\cdot}40$, is chlorogenic acid, which may be readily crystallized, and the fourth, $K > 10$, consists also of polymeric and unknown materials. (K, the distribution constant, is the ratio of concentration in the lighter phase to that in the heavier phase.) Isochlorogenic acid would be in the fourth band were it present.

The tubes containing the neochlorogenic acid were collected, ethanol was added (one-fifth the volume of the ethyl acetate layer) and the phases separated. Several further extractions of the aqueous layer with 80 per cent ethyl acetate – 20 per cent ethanol were made. These extracts were combined, concentrated, chilled and the precipitated sodium phosphate removed by filtration. The remaining sodium ions were removed by passing a 50 per cent alcohol solution through a column of 'Dowex-50'. Serious losses of neochlorogenic acid attended this operation. The eluate was concentrated *in vacuo*, whereupon crystallization occurred. Recrystallization could be effected from water or ethanol.

The ultra-violet absorption spectrum is typical of the other isomers[1]; the rotation is lower, $[\alpha]_D^{7} -5\cdot4^{\circ}$ (50 per cent alcohol); m.p. 177–179° (dec.). The crystalline nature was further shown by its characteristic X-ray pattern. *Analysis*: calc. for $C_{16}H_{18}O_9$: C, 54·2; H, 5·12. Found: C, 54·2; H, 5·44. Neutral equivalent, using as indicator the yellow-green colour formed on neutralization by base, 367; calc., 354. A similar titration with chlorogenic acid hemihydrate gave a neutral equivalent of 366 (calc. 363).

Saponification of 12·8 mgm. of neochlorogenic acid with sodium hydroxide in a nitrogen atmosphere allowed the isolation of 6·5 mgm. (91 per cent) of caffeic acid hydrate, m.p. 178–180° (uncorr.). After recrystallization from water, it was shown by mixed melting point and X-ray pattern to be caffeic acid. Quinic acid was also isolated, in poorer yield, from the non-ether soluble fraction of the hydrolysis products. It, too, was identified by mixed melting point determination and comparison of its X-ray pattern with that of an authentic specimen.

The position of attachment of the caffeoyl group to the quinic acid is not known.

I wish to thank Mr. D. R. Black and Dr. K. J. Palmer for the X-ray data and Mr. L. R. White and Miss G. E. Secor for the ultimate analyses.

A Fluorescence Test for Serotonin and Other Tryptamines

THE current interest in naturally occurring tryptamines, and the recent report by Shepherd *et al.*[1] on the detection of serotonin (5-hydroxytryptamine), prompt us to describe a more sensitive and specific test which has been used for some time in our investigations on the pain-producing agent of burn-blister fluid[2].

This test, which appears to be specific for those tryptamines which do not carry substituents at position 2 or at either of the nitrogen atoms, nor with heavily substituted side-chains, is performed thus. The solution under investigation, suitably diluted, is either spotted on to filter paper or, better, subjected to paper chromatography in an appropriate solvent system. The paper is dried in air, treated with a solution of ninhydrin in acetone (0·2 per cent) containing 10 per cent v/v of glacial acetic acid (spray or dipping technique[3]), the acetone allowed to evaporate, and the paper heated in an oven at 90–100° for 2–3 min. After heating, the paper is examined in ultra-violet light (3650 A.); an area of intense blue-green fluorescence indicates a susceptible tryptamine.

The sensitivity of this test is such that 10^{-4} μmole/sq. cm. can readily be detected on a chromatogram; this corresponds to less than 0·02 μgm. o serotonin and is far beyond the sensitivity or specificity of the simple ninhydrin or Ehrlich colour reactions, or the fluorescence tests of Shepherd *et al.* or of Udenfriend *et al.*[4]. Molar proportions of al the reacting tryptamines give very similar intensities and colours of fluorescence. The results shown in the table were obtained with tryptamine salts tested at a density on paper chromatograms of 10^{-3} μmole/sq. cm

Tryptamine substituents	Appearance after treatment	
	Colour in visible light	Fluorescence in ultra-violet light
None (tryptamin)	—	bright blue-green
5-Hydroxy (serotonin)	—	bright blue-green
1-Methyl	strong pink, slowly fading	pale green after visible colour fades
2-Methyl	—	none
α-Methyl	—	bright blue-green
α-Ethyl	—	bright blue-green
α : α-Dimethyl	—	very faint golden
N : N-Dimethyl	—	none
α-Carboxy (tryptophan)	—	none

No fluorescence is given by tryptophan at any concentration. Furthermore, the purple ninhydrin colour from tryptophan or other ammo-acid will not obscure the characteristic fluorescence of much smaller amounts of tryptamines mixed with the amino-acid. More than a hundred other amines, amino-acids and indoles have been tested, but none gives the characteristic fluorescence. The test works equally well on all types of filter-paper, including a specially purified paper, 10/*S*, supplied by Messrs. J. B. Green, Ltd., and with chromatograms run in acidic, basic or phenolic solvents (though the latter tend to destroy serotonin). The intensity of fluorescence is much reduced unless acetic acid is present in the ninhydrin reagent; this may explain why the great sensitivity and selectivity of this reaction was not noticed by Harris and Pollock, who first mentioned it[5].

The high-intensity fluorescence of the products of the reaction suggests that they are β-carboline derivatives. This view is supported by the negative results with certain substituted tryptamines. Substitution of the side-chain NH_2— would prevent condensation with a carbonyl compound; substitution at position 2 would prevent ring-closure of the condensed side-chain; di-substitution (but not mono-substitution) at the α-carbon atom would prevent dehydrogenation to the carboline; and many carbolines substituted at the indole-nitrogen have diminished fluorescence. Further investigations on the mechanism and specificity are in progress, but in the meantime the test should prove useful for studying the tryptamines in natural materials[1,4,6].

We are grateful to Prof. E. C. Dodds and Prof. C. A. Keele for their encouragement.

Effect of Tri-*ortho*-cresyl Phosphate on the Absorption of Tocopherol

IN 1943, Bloch and Hottinger[1] found that the toxicity of tri-*ortho*-cresyl phosphate to rabbits was considerably diminished when the rabbits were fed tocopherol acetate simultaneously with the tri-*ortho*-cresyl phosphate. Meunier *et al.*[2] administered tocopherol acetate daily to rabbits and determined the concentration of tocopherol in the plasma before and after feeding a lethal dose of tri-*ortho*-cresyl phosphate; it was found that tri-*ortho*-cresyl phosphate caused a pronounced fall in plasma tocopherol. These experiments have led to the supposition that tri-*ortho*-cresyl phosphate has an anti-vitamin E action.

The results obtained by Thompson *et al.*[3-5] have directed recent interest towards the demyelination and paralysis seen in chickens 10–14 days after feeding 1 ml. tri-*ortho*-cresyl phosphate/kgm. These workers pointed out that tri-*ortho*-cresyl phosphate appears to exert a highly selective inhibitory action on the pseudo-cholinesterase which is found in myelin sheaths; however, other investigators have shown that inhibition of the pseudo-cholinesterase in other species[6] or by other compounds[7] does not always result in either demyelination or paralysis. In view of the decrease in tri-*ortho*-cresyl phosphate toxicity effected by tocopherol acetate[1,2], it seemed of interest to investigate the possible antagonism between tocopherol and tri-*ortho*-cresyl phosphate in chickens.

Chickens were fed 50 mgm. D,L-α-tocopherol in 0·3 ml. arachis oil solution daily and the concentration of tocopherol in the plasma was determined daily by a modification of known methods[8,9]. The tocopherol concentration rose from about 0·2 mgm. per cent to 4 mgm. per cent after the first dose of tocopherol and to 5·5 mgm. per cent after the second dose. If the chickens were fed once with 1 ml. tri-*ortho*-cresyl phosphate/kgm. on the first day, the concentration of tocopherol in plasma failed to rise above 0·3 mgm. per cent after feeding the tocopherol. Similar results were obtained with tri-*ortho*-cresyl phosphate and tocopherol acetate.

If the concentration of tocopherol in the plasma was first raised to a high level by repeated doses of tocopherol acetate before the tri-*ortho*-cresyl phosphate was administered, it was found that the plasma concentration decreased by 60 per cent in two days after feeding the tri-*ortho*-cresyl phosphate, despite the continued administration of tocopherol acetate. The tocopherol concentration in the plasma of the control group also decreased by 60 per cent in two days when the administration of tocopherol acetate was discontinued. The apparent anti-vitamin E action of tri-*ortho*-cresyl phosphate in these experiments and in those of Meunier *et al.*[2] would thus appear to be due to the fact that tri-*ortho*-cresyl phosphate prevents the absorption of tocopherol and tocopherol acetate from the intestine.

The administration of free tocopherol does not prevent either the pseudo-cholinesterase inhibition or the paralysis caused by the administration of tri-*ortho*-cresyl phosphate. Thus when tocopherol and tri-*ortho*-cresyl phosphate are given to chickens, the latter is absorbed from the intestine but the former is not. However, when tocopherol acetate and tri-*ortho*-cresyl phosphate are given simultaneously, the pseudo-cholinesterase is only partially inhibited and the chickens do not become paralysed even after a second dose of tri-*ortho*-cresyl phosphate. Since tocopherol acetate is recovered from the plasma in the form of free tocopherol, it is apparent that neither the tri-*ortho*-cresyl phosphate nor the tocopherol acetate is well absorbed from the intestine in the above experiments. It seems highly probable that the results obtained by Bloch and Hottinger[1] must be explained on this basis.

Although tri-*ortho*-cresyl phosphate can be regarded as an 'antagonist' of vitamin E in the normal animal because it prevents this vitamin from being absorbed, the toxicity of tri-*ortho*-cresyl phosphate to chickens cannot be diminished by previous administration of free tocopherol which raises the plasma concentration to a high level[10]. The mechanism by which tri-*ortho*-cresyl phosphate prevents the absorption of tocopherol is not yet clear. However, it seems possible that tri-*ortho*-cresyl phosphate might also interfere with the utilization of other fat-soluble alcohols.

Structure of Insulin

IN a recent communication[1], I described all the structures of insulin, based on the α-helix of Pauling, Corey and Branson, which the use of atomic models had shown to be sterically possible. Arndt and Riley[2] have criticized my conclusion that an intra-chain cystine link cannot be formed between the seventh and eleventh residues of the *A*-chains. In order to form this link, Arndt and Riley have distorted the helix until it has almost a four-fold screw axis (helix angle 92°, helix translation 1·4 A.) while reducing the hydrogen-bond distance to 2·6 A.

It is doubtful whether this can be correctly or usefully called the α-helix of Pauling, Corey and Branson, and in any event it would be a structure of higher internal energy and its existence would only be favoured if the formation of the intra-chain link contributed to its stability. This, however, does not seem to be the case. In their C—S—S—C link, as compared to the values obtained from dimethyl disulphide[3], two C—C—S angles have been increased by 5°, and two C—S—S angles by 11°, while the S—S, C_β—S and C_α—C_β bond-lengths have been increased by 0·21, 0·12 and 0·03 A. respectively. The energy involved in such a degree of strain would be of the order of several kilocalories, and the tendency would be for the relevant part of the chain to unwind and form a more stable intra- or inter-hydrogen-bonded configuration. The models show that such an unwinding of the helix would be sterically possible.

Arndt and Riley are correct in saying that the α-helix should not be treated as a "perfect immutable structure"; but the point at issue is what degree of strain or distortion may be considered reasonable. The structures I put forward involved very little strain, and on the other hand no structure was rejected unless it was impossible to build it even by distorting the helices to the considerable extent which will be defined in the fuller account to be published elsewhere.

Restricted Rotation in Polar Gases near the Critical Point

David, Hamann and Pearse[1], in a recent communication in *Nature*, attributed the onset in dielectric loss to a fairly sharp transition to restricted rotation in gaseous methyl fluoride at densities somewhat above the critical value. In a subsequent publication[2], they claimed added support for this hypothesis by showing that the correlation parameter g of Kirkwood's theory[3] of dielectric polarization increases markedly above unity, the value which it would attain in the absence of such restricted rotation. It is the purpose of this communication to point out that the behaviour of g found by David, Hamann and Pearse is the result of an inappropriate method of calculation, and that the dielectric loss observed can be interpreted without any assumption of a sharp transition to a state characterized by restricted rotation.

The values of g were calculated by David, Hamann and Pearse upon the assumption that the dipole moment of the molecules is the vacuum dipole moment. This assumption is not justified, since application of the Onsager reaction field theory[4] shows that the effective moment of a molecule increases as the pressure is increased, due to the additional moment induced by the neighbouring molecules. Another correction which must be taken into account is the refinement of Kirkwood's theory to include the effect of distortion polarization[5]. Values of g obtained by means of the modified equation and the effective dipole moment do not show the qualitative trend reported by David, Hamann and Pearse, and in fact indicate that any restriction of rotation must be extremely small. Values of g calculated, first, by David, Hamann and Pearse; secondly, by the use of Kirkwood's equation and the appropriate dipole moment; and finally, by the modified equation, are shown in the accompanying table. The scattering of values of g about unity observed in column 3 of the table indicates that so far as this calculation is concerned no definite evidence exists for restricted rotation. The values of g below unity at the higher pressures may be ascribed to the larger experimental errors incurred under these conditions. However, it should be pointed out that contra-association ($g < 1$) is observed in several liquid alkyl halides[6], and that a decrease in g at high densities is not unexpected.

CORRELATION PARAMETER OF METHYL FLUORIDE AT 50° C.

Density (moles/L.)	g (D., H. and P.)	g (Kirkwood eq.)	g (H. and A. eq.)
0·960	1·00	1·00	1·00
2·266	1·02	1·00	0·99
3·997	1·04	1·02	1·00
6·60	1·08	1·04	1·00
7·70	1·15	1·05	1·00
8·83 — d_c			
9·24	1·18	1·05	1·00
10·28	1·19	1·07	0·99
11·78	1·23	1·08	0·98
12·97	1·30	1·09	0·99
14·02	1·33	1·10	0·98

The process described by David, Hamann and Pearse of lining up the molecules like cigars in the gas phase, that is, a sudden transition to a rotationally ordered state, cannot occur in a gaseous system, as has been shown in a general way by statistical mechanical methods[6]. However, a gradual increase in directionally dependent interaction is, of course, possible as the density is increased, and is in fact indicated by the dielectric loss measurements. Although such interaction should increase rapidly near condensation regions, and therefore near the critical point, the increase is not peculiar to the critical density, and should occur at increasingly greater densities as the temperature is increased above the critical value.

We therefore suggest that the phenomenon observed by David, Hamann and Pearse is due to the increased coupling of molecules as the distances between them is decreased.

For molecules where the angularly dependent component of the intereaction potential is much stronger as, for example, in HF, the lining up of molecules in the gas phase is more pronounced, but even then no sharp 'rotational phase change' is possible.

Measurements of the Terrestrial Magnetic Field in the *E*-Layer

IN a previous communication[1], we remarked briefly that gyrointeraction of radio-waves gives the measure of the total intensity H of the earth's magnetic field in the lower part of the E-layer, which extends approximately 90–95 km. above ground-level. This measurement reveals the presence of the electric currents in the E-layer which are postulated to account for terrestrial magnetic variations. The method is the only one by which H can be measured continually in the E-layer. It is only necessary to find

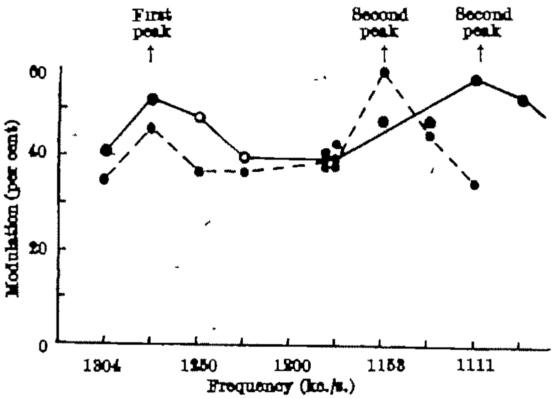

Fig. 1. Results of experiments made on June 7, 1950 (full curve), and on June 30, 1951 (broken curve)

esonance curves with two maxima lying equidistant rom the local gyrofrequency[1]. The mean value of wo frequencies at the position of the maxima is the gyrofrequency Ω. Because $\Omega = eH/2\pi mc$ [1], where e s the electronic charge, m is the electronic mass and is the velocity of light, it is possible to calculate H. Table 1 shows values of H found in Italy by gyro-nteraction.

An easier method, which is at the same time ufficiently precise, is self-demodulation of radio-waves, a phenomenon recently observed by me[2]. This phenomenon is substantially different from gyro-nteraction.

If the radio-wave from a transmitter is modulated, for example, at 230 c./s., with the percentage modulaion kept strictly constant at 80 per cent, and its carrier frequency varied around the local gyrofrequency (in the case of Fig. 1 from 1,276·1 to ,090·9 kc./s.), we find that at a receiving station at least 200 km. distant from the transmitting tation the percentage modulation of the signal varies as shown in Fig. 1. The minimum of the percentage of modulation received (the maximum of demodulaion) is at the gyrofrequency. The mean value of the frequencies at which maxima of Fig. 1 lie gives the gyrofrequency and, from the formula $\Omega = eH/2\pi mc$, H in the E-layer can be calculated. To measure the gyrofrequency, it is sufficient for a station to radiate power of only 3–5 kW., but it should be able to vary ts carrier-frequency continuously about the local gyrofrequency. The receiving station consists of a selective receiver tuned to the transmitter, with its ntermediate-frequency output coupled to an oscillograph. The envelope of the oscillograph trace gives a measure of the percentage of modulation. It is desirable to take a number of measurements at each carrier-frequency emitted. In Fig. 1 every point is the mean value of many measurements.

Table 1

Date	Method	Locality of emitting station	Locality of receiving station	Sky-point to which H value is referred	H (oersted)
3.7.1949	Gyrointer-action	Florence	Turin	Monte-falco (Foligno)	0·434
6.7.1949	Gyrointer-action	Florence	Turin	Monte-falco	0·431
13.7.1949	Gyrointer-action	Florence	Turin	Monte-falco	0·423
7.6.1950	Self-de-modulation	Florence	Turin	44° 25′ N. 9° 27′ E.	0·424
23.7.1950	Self-de-modulation	Florence	Naples	42° 18′ N. 12° 54′ E.	0·430
29.7.1950	Self-de-modulation	Florence	Naples	42° 18′ N. 12° 54′ E.	0·443*
30.6.1951	Self-de-modulation	Florence	Turin	44° 25′ N. 9° 27′ E.	0·432

* Probably because the frequency of the first maximum does not occur.

Table 1 contains some values of H found in Italy by self-demodulation. The degree of precision may reach the third decimal figure. The small changes of the frequencies on which the maxima lie show the variations of the magnetic field in the ionosphere. As H at ground-level during the experiments was 0·4477 oersted, we see that H in the E-layer is smaller than on the earth.

Further details of the method will be given in *Il Nuovo Cimento*.

A Method of Changing the Isotope Abundance in Mercury

In order to investigate the possibility of changing the isotope composition of mercury merely by passing a direct electric current through it under certain conditions, the following experiments were carried out.

Mercury of analytical grade was distilled under vacuum in a 'Pyrex' glass apparatus and was then sucked up into a glass cell fitted with tungsten electrodes (see Fig. 1). The diaphragm tube was 140 mm. long and 2 mm. inside diameter, and was filled with glass beads (0·09–0·15 mm. diameter) between two sintered glass plates, forming the top and the bottom of the diaphragm. 1·430 gm. of mercury above the diaphragm made contact with the top electrode. A direct current was passed through the cell with the negative electrode at the bottom.

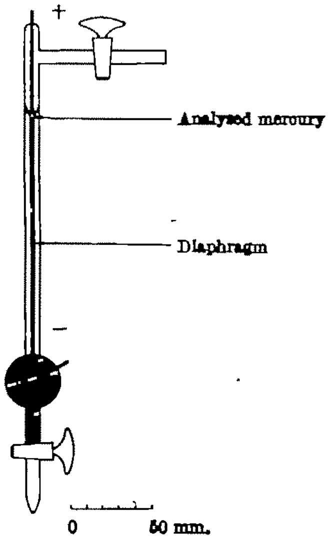

Fig. 1. Mercury cell

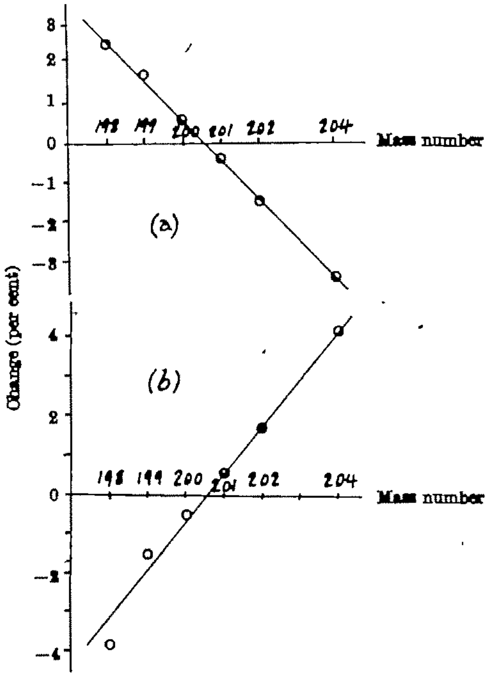

Fig. 2. Change in relative isotope abundance in the mercury above the diaphragm of apparatus shown in Fig. 1. (a) Top electrode positive. (b) Top electrode negative

The whole cell was immersed in a constant-temperature bath at 15° C. The experiment lasted about 2,000 hr. The mean voltage was 3·40 V. and the mean current 22·6 amp. Immediately after the current was shut off, the mercury above the diaphragm was removed. This mercury has been analysed by the mass spectrometer group at this laboratory and was then compared with a control sample of the mercury used. The result is given in Table 1 and Fig. 2 (*a*).

Another experiment was carried out in the same way except that the current direction this time was changed and the top electrode was made negative. In this case also the mercury above the diaphragm was taken for analysis. The result is given in Table 2 and Fig. 2 (*b*).

The results of these two experiments indicate the rather surprising effect that the light isotopes of mercury are enriched at the anode end of the cell and the heavy isotopes at the cathode.

Similar experiments have been made with amalgams and with a solid metal wire; but as yet it has not been possible to study the isotopic compositions of these samples.

Table 1. (Top electrode positive)

Mass number	Relative abundance (per cent)		Change in relative abundance* (per cent)
	Control sample	Cell sample	
198	10·10	10·35	+ 2·5 ± 0·3
199	17·05	17·35	+ 1·70 ± 0·2
200	23·25	23·40	+ 0·6 ± 0·2
201	13·27	13·22	− 0·4 ± 0·2
202	29·60	29·15	− 1·54 ± 0·2
204	6·67	6·44	− 3·45 ± 0·2
	99·94	99·91	—

* The error given with each value of the change in relative abundance is the maximum deviation in a series of six measurements.

Table 2. (Top electrode negative)

Mass number	Relative abundance (per cent)		Change in relative abundance (per cent)
	Control sample	Cell sample	
198	10·06	9·68	− 3·8 ± 0·4
199	17·03	16·78	− 1·5 ± 0·3
200	23·32	23·20	− 0·5 ± 0·3
201	13·27	13·35	+ 0·6 ± 0·3
202	29·60	30·10	+ 1·7 ± 0·2
204	6·66	6·94	+ 4·2 ± 0·4
	99·94	100·05	

The same sort of diaphragm as that used here h been used by A. Klemm *et al.*[1] in experiments c the electrolysis of fused salts. K. Schwartz[2] h made density measurements after passing 9·6 × 1 coulombs through 100 gm. of mercury in a cell which the anode and cathode compartments we connected by a capillary, but no change in abundan of the isotopes was detected.

Interaction between Surfaces in Close Proximity

ACCORDING to theories of the interaction of doub layers[1,2], two surfaces in close proximity are mutuall repelled by a force which increases as the surfac are brought together. Therefore, if an air bubb is pressed against a plane glass surface under wate the disjoining film of water should reach an equil brium thickness at which the double layer repulsio is balanced by the excess pressure of the bubble.

By an interferometric method, Derjaguin an Kusakov[3] showed that this equilibrium thickne was about 1000 A., and, as was expected, varied wit the excess pressure. Later, Elton[4] showed co clusively that, given sufficient time, the disjoinir film between a bubble and a silica surface thinne to well below 200 A., and claimed, therefore, that tl films observed by Derjaguin and Kusakov were n at equilibrium, but were thinning at a slow bu measurable rate. The latter authors have since r affirmed their earlier conclusions[5].

The results of similar experiments in this laborator may resolve this controversy. When extreme care taken to exclude surface-active impurities, Elton results are duplicated for both silica and glass surface However, in a solution containing 3 × 10⁻⁴ mol sodium hexadecyl sulphate an equilibrium fil approximately 1000 A. thick is obtained, whic responds to changes in bubble pressure, temperatu variation and electrolyte concentration, in precisel the same way as did the films which Derjaguin an Kusakov obtained in what they described as 'pur water. It has been found extremely difficult t prevent the same effect arising from contaminatic of the bubble surface, and the results of Derjagui and Kusakov are almost certainly due to suc accidental contamination. The existence of a quilibrium film of measurable thickness in solutions : sodium hexadecyl sulphate thus presents the ossibility of measuring the repulsion between double yers under known conditions.

A special precaution must be taken when making ese measurements in dilute solutions of surface-ctive substances, because of the slow attainment of rface tension equilibrium. As adsorption proceeds, e limited volume of solution in the disjoining film more rapidly depleted of adsorbent than the free lution, so that, after a time, adsorption proceeds t a lower rate on the flattened portion of the bubble rface than elsewhere. Under the surface tension radient set up, surface diffusion takes place, with e result that liquid is continually carried into the isjoining film by surface transport[6]. If this rate of flow should equal the rate of outflow due to the xcess bubble pressure, one may wrongly gain the npression of an equilibrium film of excessive thickess. Thus one must ensure that adsorption is complete before making the measurements.

Pancreatic Lipase: a Scheme of its Specificity and a Hypothesis of the Mechanism of its Action

THE specificity of pancreatic lipase has not hitherto been readily defined. Lipase can hydrolyse many esters, but acts best on those derived from long-chain fatty acids[1]. Less attention has been paid to the effect on esterolysis of that part of the ester derived from the alcohol; glyceryl and benzyl groups have been found to influence the reaction most favourably, while aliphatic groups exercise a restraint which increases with the length of their carbon chain[2].

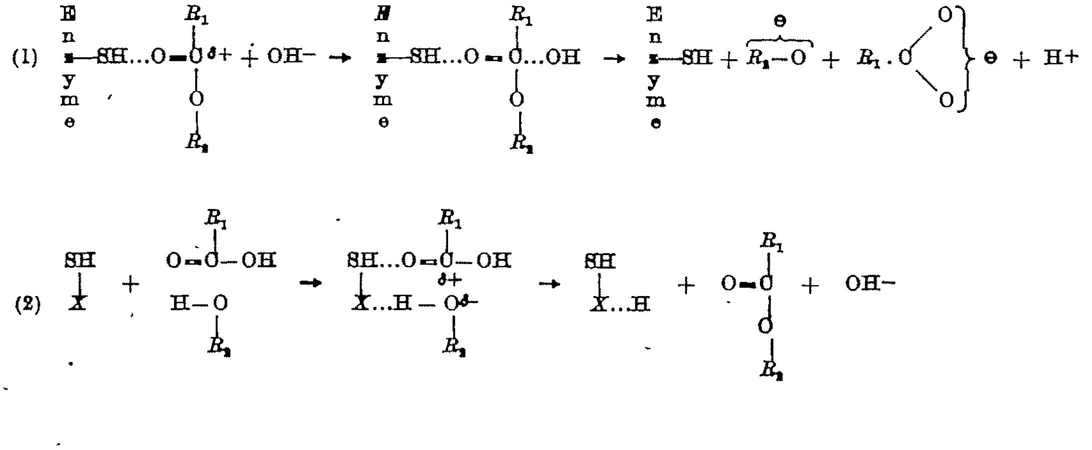
From the available evidence[1], the following conditions appear to be necessary for lipase to exert its optimal action: (1) the acid residue should be electron donating; (2) the alcohol residue should be electron attracting.

The action of lipase is inhibited by aldehydes and ketones with an intensity which increases with the size of the alphyl group attached to the carbonyl group. The inhibition is especially strong when the carbonyl group is adjacent to a phenyl nucleus, as in benzaldehyde or acetophenone[3,4]. Thus high affinity for the enzyme in esters, aldehydes and ketones is associated with a structure which produces a high electron density at the 'carbonyl' oxygen, either by an inductive or a mesomeric effect. On this basis, pancreatic lipase may be defined as a hydrolase specific for organic esters, which have an affinity for the enzyme proportional to the size of the negative charge at the 'carbonyl' oxygen.

It is suggested that the nucleophilic oxygen reacts with an electrophilic centre on the enzyme, and that this centre is the —SH group which is essential for the action of lipase. Between the two groups a hydrogen bond can form. In consequence, electron density at the 'carbonyl' carbon decreases and approach of hydroxyl ions is facilitated (1). The ease of hydrolysis of the substrates of lipase in non-enzymic alkaline conditions varies inversely with their ability to undergo cleavage by lipase, but varies directly with the tendency to form this hydrogen bond, in the lower members of the series. Synthesis may be facilitated in a similar way 2); that is, hydrogen bonding occurs between the alcoholic hydrogen and a strongly electronegative centre, X, on the enzyme, as well as between the 'carbonyl' oxygen and the —SH group. The two hydrogen bonds increase the difference in charge between the 'carbonyl' carbon and the alcoholic oxygen, and therefore reduce the activation energy for the esterification reaction.

The balance between synthesis and hydrolysis depends on the hydroxyl ion concentration. On this basis synthesis in alkaline media containing only the carboxyl anion would be unlikely. So far as is known, no synthesis has been reported in any but an acid medium[5].

It is implied that there is only one link between substrate and enzyme during hydrolysis, and two during synthesis. The strongly favourable influence exerted by some alcohol residues on hydrolysis is therefore attributed to their ability to stabilize the ion $\overset{\ominus}{\overbrace{R{-}\mathrm{O}}}$, and their capacity for withdrawing electrons, which directly assist the function of the hydrogen bond. In other words, the dominating factor in the combination of ester with lipase is the structure



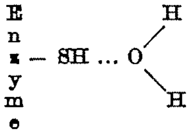
$$(1)\quad \text{Enzyme}{-}\mathrm{SH}\ldots\mathrm{O}{=}\overset{R_1}{\underset{\mathrm{O}R_2}{\mathrm{C}}}{}^{\delta+} + \mathrm{OH}^- \rightarrow \text{Enzyme}{-}\mathrm{SH}\ldots\mathrm{O}{=}\overset{R_1}{\underset{\mathrm{O}R_2}{\mathrm{C}}}\ldots\mathrm{OH} \rightarrow \text{Enzyme}{-}\mathrm{SH} + \overset{\ominus}{\overbrace{R_2{-}\mathrm{O}}} + \left.R_1\cdot\mathrm{C}\begin{matrix}\mathrm{O}\\ \mathrm{O}\end{matrix}\right\}\ominus + \mathrm{H}^+$$

$$(2)\quad \begin{matrix}\mathrm{SH}\\ |\\ X\end{matrix} + \begin{matrix}\mathrm{O}{=}\overset{R_1}{\mathrm{C}}{-}\mathrm{OH}\\ \mathrm{H}{-}\mathrm{O}{-}R_2\end{matrix} \rightarrow \begin{matrix}\mathrm{SH}\ldots\mathrm{O}{=}\overset{R_1}{\underset{\delta+}{\mathrm{C}}}{-}\mathrm{OH}\\ X\ldots\mathrm{H}{-}\mathrm{O}^{\delta-}{-}R_2\end{matrix} \rightarrow \begin{matrix}\mathrm{SH}\\ |\\ X\ldots\mathrm{H}\end{matrix} + \mathrm{O}{=}\overset{R_1}{\underset{\mathrm{O}R_2}{\mathrm{C}}} + \mathrm{OH}^-$$

of the acid, while the alcohol moiety plays a part in the ease of breakdown of the complex.

The benzoates have considerable affinity for lipase, probably because of the conjugation of the 'carbonyl' group with the phenyl nucleus, but this conjugation must be lost on hydrolysis. The enzyme is apparently incapable of facilitating this process, with the result that the benzoates are not more easily hydrolysed when in combination with the enzyme than they are in the free state[3]. It seems that the enzyme is best suited to overcome unfavourable influences on hydrolysis due to inductive effects.

If this hypothesis is correct, other hydrogen-bonding substances will combine with the enzyme. This may be the mechanism of the inhibition exerted by fluoride ions[4]. Similarly, combination with water is possible.



This reaction may explain the apparently slight affinity for lipase shown by substrates (for example, triacetin, tripropionin and 'Tween 20'[7]) in homogeneous solution, although when an oil–water interface is present the affinity is very much greater[8]. The surface-active properties of lipase tend to bring it to such an interface[5], where the concentration of water is small compared with the concentration of substrate. The linear relationship between the concentration of triacetin and the rate of hydrolysis[9] may perhaps be due to competitive inhibition by water.

This hypothesis attributes to the enzyme the function of inducing, by means of hydrogen bonding, electronic shifts at appropriate points in the substrate, thereby speeding up the reactions which these compounds normally but with difficulty undergo. Surface-action effects, which are very important in catalysis by lipase, probably enhance the efficiency and specificity of this process.

Errors in the Estimation of Serial Correlations

Since the introduction of the serial correlation coefficient by Yule[1] the method of correlogram analysis has been extensively used. As a rule, the correlogram analysis has been preceded by a smoothing process for the removal of trend (either by curve fitting or moving averages), and the serial correlations are estimated from the residuals. Although it is quite generally realized that parameters so estimated are liable to bias, the form and full extent of this bia have not been extensively investigated.

These biases may have serious effects on the practical analysis of time series. The removal of an fitted constants will affect the correlogram, and test of goodness of fit will be vitiated. In particular, th moving average method of trend elimination ma give rise to a correlogram entirely different from tha of the parent process.

The bias arises from two sources. In the firs place, the serial correlation coefficient is the rati of the serial covariance to the variance of the series When these quantities are estimated from the dat they are themselves subject to sampling error, an so the expectation of their ratio is not in genera equal to the parent serial correlation. This bia always reduces the absolute value of the seria correlation, and disappears only when the parent serial correlation is zero. Secondly, the fitting o constants to the series introduces further bias. For example, when the mean is estimated from the data, a negative bias is introduced into the estimated serial covariance, reducing the value of the serial correlation.

When the mean only is fitted from the data, the serial correlation may be estimated as:

$$r_k = \frac{\dfrac{1}{n-k}\left\{\sum\limits_{i=1}^{n-k} x_i x_{i+k} - \dfrac{1}{n-k}\left(\sum\limits_{i=1}^{n-k} x_i\right)\left(\sum\limits_{i=1}^{n-k} x_{i+k}\right)\right\}}{\dfrac{1}{n}\left\{\sum\limits_{i=1}^{n} x_i^2 - \dfrac{1}{n}\left(\sum\limits_{i=1}^{n} x_i\right)^2\right\}}$$

Using this definition, the biases in the serial correlations may be found in special cases. For example, for the moving average $x_t = \epsilon_{t-1} + \epsilon_t$,

$$E(r_1) = \frac{1}{2} - \frac{3}{2n} + 0\left(\frac{1}{n^2}\right),$$

so that the bias, to order $1/n$, is $-3/2n$. For the Markoff process $x_t = \rho x_{t-1} + \epsilon_t$,

$$E(r_1) = \rho - \frac{1+3\rho}{n} + 0\left(\frac{1}{n^2}\right).$$

These biases are larger than has generally been supposed. For example, for a Markoff process with parameter 0·8, the expectation of r_1 in a series of twenty terms when the mean is estimated is 0·630. The only previous work on this subject is by Sastry[2]. He calculated the bias due to fitting the mean, but neglected the first source of bias mentioned above, and in consequence the biases he gives are much too small. For example, using a slightly different definition of r_1, he gives the expectation of r_1 in series of twenty terms from a Markoff process with parameter 0·8 as 0·690, under-estimating the bias by 35 per cent.

Extensive calculations have been carried out on artificially constructed stochastic series confirming these results. Work is at present in process on the effect of various methods of trend removal, and detailed accounts will be published elsewhere.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 26

Nutrition Society (joint meeting with the Royal Geographical ociety, at the Royal Geographical Society, Kensington Gore, London, .W.7), at 2.30 p.m.—Symposium on "The Provisioning of Expeditions n the Field".

British Society for the History of Science (in the Lecture Room of the Science Museum, South Kensington, London, S.W.7), at 5.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: "The Work of Robert Hooke".

Institution of Electrical Engineers, Radio Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Long-Playing Disk Records Compared with Magnetic Tape for Sound Reproduction n the Home".

London School of Hygiene and Tropical Medicine (at Keppel Street, London, W.C.1), at 5.30 p.m.—Dr. Paul Russell: "The Unfolding of Malaria Etiology" ("Man's Mastery of Malaria", 1) (Heath Clark Lecture).* (Further Lectures on October 27, 28, 29 and 30.)

Tuesday, October 27

Co-ordinating Advisory Committee on Oil Pollution of the Sea, L.O.B.P., British Section (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 11 a.m.—Conference on "Oil Pollution of the Sea" (admission by ticket, obtainable from Miss P. Barclay-Smith, Secretary of the above Committee, c/o British Museum (Natural History), Cromwell Road, London, S.W.7).

University College, London (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. R. H. Garstang: "Life on Other Worlds".*

Communications Research Centre (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. J. Ayer: "What is Communication?"*

Royal Society of Medicine, Experimental Medicine and Therapeutics Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Discussion on "Survival of Tissue at Low Temperatures".

Birkbeck College (at Malet Street, London, W.C.1), at 6 p.m.—Prof. W. S. Bullough: "The History of Hormones".*

Society of Instrument Technology (at Manson House, 26 Portland Place, London, W.1), at 6.30 p.m.—Mr. A. R. Aikman, Mr. J. McMillan and Mr. A. W. Morrison: "Static and Dynamic Performance of Sheathed Industrial Thermometers".

Wednesday, October 28

Postgraduate Medical School of London (at Ducane Road, Shepherd's Bush, London, W.12), at 2 p.m.—Prof. G. F. Marrian, F.R.S.: "Steroid Metabolism".* (Further Lectures on October 29 and 30.)

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. L. G. Brazier: Chairman's Address.

Society of Chemical Industry, Food Group—Nutrition Panel (in the Rooms of the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. A. E. Bender: "Nutritional Reappraisal—Proteins".

Wednesday, October 28—Friday, October 30

Institute of Petroleum, Hydrocarbon Research Group (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2)—Conference on "Applied Mass Spectrometry".

Thursday, October 29—Friday, October 30

Association of Special Libraries and Information Bureaux (at Bradford)—Northern Branch Conference.

Friday, October 30

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Dr. D. F. Galloway: "Some Practical Aspects of Cutting Tool Nomenclature Arising from Recent Research".

North East Coast Institution of Engineers and Shipbuilders (at the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6.15 p.m.—Dr. C. Sykes, F.R.S.: "Internal Stresses in Some Types of Forgings" (Andrew Laing Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—The Right Hon. Lord Samuel: "Philosophy and Present-Day Physics".

Saturday, October 31

Association of Clinical Biochemists, N.W. Region (in the Department of Physiotherapy, Crumpsall Hospital, Manchester 8), at 2 p.m.—6th Scientific Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (with honours degree in civil engineering or equivalent qualifications, and professional or industrial and teaching experience) in Civil Engineering—The Director, Robert Gordon's Technical College, Aberdeen (October 28).

Assistant (Grade B) (interested in research) in the Department of Mathematics, Technical College, Bradford, to undertake work at degree level—The Director of Education, Town Hall, Bradford (October 29).

Superintendent (Superintending Scientist) (with university degree of high standard in physical science or engineering, and extensive experience in research and development work, including the directing of such work) at the Long Range Weapons Establishment, Missile Flight Research Division, Salisbury, South Australia, to direct research and development work concerned mainly with the behaviour of guided missiles in flight—The Senior Representative, Departments of Defence, Production and Supply, Australia House, Strand, London, W.C.2 (October 29).

Graduate in Physics (with good theoretical knowledge of refrigeration, and preferably with practical experience of absorption systems) at the North Thames Gas Board Laboratories, Watson House, Fulham, London, S.W.6, to carry out research and development on absorption refrigerators—The Staff Controller, North Thames Gas Board, 30 Kensington Church Street, London, W.8, quoting 666/109 (October 30).

Research Fellow in Pure Mathematics—The Registrar, The University, Edgbaston, Birmingham 15 (October 30)

Assistant Lecturer in Chemistry—The Registrar, University College, Leicester (October 31).

Biochemist (honours science graduate) primarily for research duties in the Geriatric Department of the Sunderland Hospital Group—Senior Administrative Medical Officer, Newcastle Regional Hospital Board, "Blythswood South", Osborne Road, Newcastle upon Tyne 2 (October 31).

Lecturer (preferably with special interest in some branch of applied mathematics) in Mathematics—The Registrar, College of Technology, Manchester 1 (November 2).

Chief Engineer to the London Electricity Board—The Chairman, London Electricity Board, 46 New Broad Street, London, E.C.2 (November 6).

Assistant Lecturer in Geography—The Registrar, Trinity College, Dublin (November 7).

Research Assistant (with good honours degree in zoology, special interest in the problems of animal behaviour, and some knowledge of physiology, experimental psychology or physics) at the Dove Marine Laboratory, to assist in researches into the behaviour of fishes of commercial importance and in the compilation of existing data on this subject—The Registrar, King's College, Newcastle-upon-Tyne (November 7).

Lecturer (preferably with special interest in electronic and/or communication engineering) in Electrical Engineering—The Registrar, College of Technology, Manchester 1 (November 9).

Assistant (graduate in chemistry, and postgraduate experience in biochemistry) in Biochemistry, for research at the Institute of Orthopaedics Biochemical Laboratories, Stanmore—The Dean, Institute of Orthopaedics, 234 Great Portland Street, London, W.1 (November 10).

Assistant in Natural History—The Secretary, The University, Aberdeen (November 15)

Assistant Director (graduate in engineering, physics, chemistry or microbiology, and experience of research in the preservation, processing and transport of food, preferably fish) at the Fishing Industry Research Institute, Cape Town, South Africa—The Secretary, P.O. Box 1233, Cape Town, South Africa (November 16).

Research Assistant in Mining (graduate in science or engineering, and preferably with some qualifications or experience in hydraulics)—The Registrar, The University, Leeds 2 (November 16).

United Steel Companies Research Fellowship in Metallurgy—The Registrar, The University Sheffield (November 18).

Lecturer in Physiology at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (New Zealand, November 30).

Lecturer in Geography—The Registrar, University College, Aberdeen (December 30).

Chair of Physics—The Registrar, University College, Hull (January 16).

Agronomist (with good honours degree, preferably in botany or natural science, and at least two years appropriate postgraduate experience) at the West African Institute for Oil Palm Research, Nigeria, for work in connexion with improvement of the cultivation of the oil palm, including fertilizer and cultural trials—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.87/11/08.

Assistant Entomologist (preferably with honours degree in zoology, specializing in entomology, and experience in rearing of live insects, and knowledge of standard laboratory techniques) in the Research Branch of the Forestry Commission, Alice Holt, Surrey, to take general charge of laboratory investigation and raising stocks of parasites, predators, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.321/53A.

Chemists (with at least H.S.C. (science) or equivalent, but further training in chemistry to H.N.C., A.R.I.C. or degree may be an advantage) in the Ministry of Supply Atomic Weapons Research Establishment, Aldermaston, Berks, for work on analysis, gases, organic compounds (microcombustion techniques), metals (trace impurities); radio chemistry; chemical services, including testing of effluents and control of chemical processes—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.485/53A.

Experimental Officer and an Assistant Experimental Officer (with a degree in agriculture, botany or chemistry) at the Grasslands Research Institute, Hurley, Maidenhead, and Drayton, Stratford on Avon, to assist in experimental work on the development of grass roots, grazing experiments or in the chemistry department—The Secretary, Grassland Research Station, Hurley, Maidenhead.

Honours Graduate (with experience in use of infra-red spectrophotometer) required to assist in programme of research on various substances isolated from dairy products—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting 53/14.

JUNIOR ASSISTANT CHEMIST (with at least a pass degree in subjects which must include chemistry) for work at Tilbury in connexion with a survey of the Thames Estuary—The Establishment Officer, Port of London Authority, Trinity Square, London, E.C.3.

JUNIOR RESEARCH ENGINEERS (with good honours degree) for (a) general automobile engineering problems; (b) for investigations concerning mechanical properties (in particular fatigue strength) of materials and components; RESEARCH ASSISTANTS (H.N.C. or equivalent qualifications) for general automobile engineering problems—The Director, Motor Industry Research Association, Lindley, near Nuneaton.

LECTURER and an ASSISTANT LECTURER (with special knowledge of cytology, genetics, ecology, taxonomy or anatomy) IN BOTANY—The Registrar, The University, Nottingham.

PHYSICISTS (with good honours degree, and some experience in training or research) for work on textile problems—The Secretary, British Rayon Research Association, Barton Dock Road, Urmston, near Manchester.

PHYSIOLOGIST (with good honours degree in physiology or equivalent qualification, and research experience, preferably involving the perfusion of isolated organs) for research on the physiology of lactation—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting 53/3.

SENIOR AGRICULTURAL OFFICER (Irrigation) (with a degree in agricultural science and practical experience of the operation of irrigation schemes) with the Gold Coast Government—Commissioner for the Gold Coast, Melbourne House, Aldwych, London, W.C.2.

SENIOR LECTURER (preferably with higher degree in either agricultural, veterinary or pure science) IN PHYSIOLOGY OF THE SHEEP, at the Massey Agricultural College, Sheep Husbandry and Wool Department, to lecture on the physiology of growth and reproduction in the sheep and the nutrition of sheep—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1, or The Registrar, Massey Agricultural College, Palmerston North, New Zealand.

SENIOR LECTURER IN TECHNICAL CHEMISTRY—The Secretary, Royal Technical College, George Street, Glasgow, C.1.

PHOTO-RECORDING

— an able helper for the engineer

Every day engineers the world over use photo-recording techniques to help them solve design and production problems. These techniques provide them with valuable information about high-speed electrical and mechanical phenomena, obtainable in no other way.

Kodak Ltd. manufacture a range of sensitized materials especially for photo-recording work.

THE BRITISH ASSOCIATION

DR. W. E. SWINTON was well entitled to claim, in his presidential address to Section X (Assembly of Corresponding Societies) of the British Association meeting at Liverpool, that he had entered the gateway which Sir Edward Appleton had held open in his presidential address to the Association on the previous evening. Dr. Swinton's address essentially was an exploration or review of the ways in which the corresponding societies, individually and in concert, can further the pursuit of science for its own sake and the consequent enrichment of the life of the community, to which Sir Edward had referred. In this, moreover, Dr. Swinton was following the example of some of his predecessors in the presidential chair of the Conference of Delegates of Corresponding Societies, since the Conference was first constituted at the Aberdeen meeting of the Association in 1885.

Particularly in the opening years of this century, the Conference was concerned with the possibility of strengthening the work of the corresponding societies and with the opportunities for scientific work which were still presented to them in certain fields. Prof. (later Sir) Ray Lankester's reference, in his presidential address to the Association at Bradford in 1900, to the decline in the numbers and activities of the field naturalists led to various suggestions when the Conference next met in 1901, at Glasgow, and a resolution was adopted by the Conference at Southport in 1903, supporting the suggestion made by Sir Norman Lockyer in his famous address, "The Influence of Brain-Power on History", that scientific workers and persons interested in science be so organized that they may exert permanent influence on public opinion, in order more effectively to carry out the third object of the Association—"to obtain a more general attention to the objects of science and the removal of any disadvantages of a public kind which impede its progress".

Sir Norman Lockyer's suggestion led directly to the formation of the British Science Guild; but the Conference continued to concern itself with the possibilities and opportunities for local work and for influencing local opinion in matters affecting science. At Dublin, in 1908, Prof. (later Sir) Henry Miers addressed the Conference on the educational opportunities of local scientific societies and their contribution to adult education, and adult education was the theme of Dr. F. A. Butler's presidential address to the Conference at Burlington House in 1918. Sir John Russell's address to the Conference at Oxford in 1926 is notable for the encouragement it gave alike to the amateur worker and to the local scientific society; and the present constitution of the Assembly, now one year old, affords even better opportunities for fulfilling the continuing functions of systematic observation and of co-operation, whether in the organization of work or in the exposition of science.

What is new about Dr. Swinton's address, accordingly, is not so much his conception of the work of the corresponding societies as his critical re-examination of the functions of both the Association and of the Assembly and its constituent societies in the light of the environment and the climate of opinion in which they are set to-day. He is conscious not only of the deepened sense of public responsibility on the part of men of science, of the wide public interest displayed in the annual meetings of the British Association, and the steps which have already been taken, in the new series of lectures for younger persons, for example, to extend the influence of the Association in making known the advances of science and their implications. He is conscious, also, of the great change in the educational background which has taken place since the Conference of Corresponding Societies was constituted.

The circumstances are changing, rather than new; but when contrasted with those of even a quarter of a century ago, they show differences sufficiently marked to justify fully Dr. Swinton's plea that the work of the Sections and of the Assembly should be reconsidered in the light of present opportunities and responsibilities, and with the view of furthering a more lasting interest in certain aspects of science than can be engendered during the annual meeting. Dr. Swinton points out that the fundamental idea of the Association as a body for explaining the trends of science generally finds expression only in the presidential address and in a few other meetings such as the evening discourses or those arranged by the Division for Social and International Relations of Science. Some of the joint meetings of the Sections, even on highly technical subjects, have attracted large audiences, and the level of exposition has on occasion been high, even from a popular point of view. This cannot be said of all joint discussions, however. Nevertheless, there is some substance in Dr. Swinton's argument that, however wide the appeal of the presidential address, the programmes of the sections tend to become more specialized.

The fact that others have, since the Liverpool meeting, suggested that the British Association may need to take account of two differing audiences—the general public and the specialists who form the nucleus of the sectional meetings—indicates that this may be an appropriate time for the Association to reconsider its functions and the audiences which it is addressing. Nor should it be forgotten that while, as Dr. Swinton rightly argues, the advance of science is so rapid and the increase of workers so considerable that a week is too short a period for the workers in one group to learn about the recent advances of their fellows, the sections fulfil another and possibly more important function. Disregarding for the moment the question whether, seen against the background of scientific meetings which take place throughout the year, the sectional meetings are the appropriate occasion for the communication of results from one specialist to another, the sectional meetings undoubtedly are an important means for interchanging knowledge across the scientific disciplines. In all sectional meetings a considerable proportion of the scientists present are now those trained in or practising some other discipline than that of the particular section holding the meeting. Quite possibly to an increasing extent the British Association meeting now provides an outstanding opportunity for the scientist attending it to learn about or discuss advances or trends in some discipline other than that with which he is immediately concerned.

This tendency is certainly sufficiently pronounced to require more consideration than some sections at present appear to give it. In facilitating such interdisciplinary exchanges as well as in the arrangement of discussions on subjects which are the concern of several scientific disciplines, the Association is performing one of its most valuable services to science to-day, and this function should not be overlooked in considering Dr. Swinton's call to the Assembly of Corresponding Societies to take up the function of accountant for science. He suggests that that Assembly is particularly suited to render a public account of the progress of science and provide an annual forum for questions and even answers. The meetings of the Assembly are no longer confined to delegates of the Societies but are open to any who care to attend. They are also more numerous, and on both counts the Assembly is better placed to discharge the responsibility taken over from the former Conference of Delegates to discuss propositions regarding the promotion of more systematic observations and plans of operation and of greater uniformity in the method of publishing results.

It is in this context that Dr. Swinton examined the question of how far the Assembly can help inquirers for scientific information not only during the local opportunities of the meeting, but also on a more permanent and wider basis, and he was concerned not simply with the diffusion of scientific knowledge or information but equally with helping people, both young and old, to engage in scientific work whether for pleasure or as professional occupation. On both counts regard must be had to the general educational position in Britain, and while he suggested that the Assembly's main task would lie in the field of adult education, he indicated the need for some further inquiry into the position of the scientific societies, more especially the local societies, the reasons for their diminishing membership and their general difficulties of publication and the like. Such inquiry involves also inquiry into the teaching of science in schools and whether such teaching really stimulates interest in science either for its own sake or as a career. That can have a close bearing on the shortage of science teachers and of technologists, for example: as Sir Charles Morris remarked at the recent Headmasters' Conference, the firing of imagination which determines careers is often the work of a teacher.

Dr. Swinton's own more specific suggestions were in regard to adult education, and especially for closer co-operation between those three major avenues of adult or self-education—the museums, the public libraries and the local scientific societies. Such co-operation must be conceived in the light of the education system of to-day, and the research committee which he advocated would, in the first instance, co-operate with the Library Association, the Museums Association, the Unions of Scientific Societies, the

Further Education Section of the B.B.C. and such of the local educational authorities as could be interested. He also advocated a series of booklets giving the outline of educational courses in the sciences, of sources of information for adults, and a guide for young people as to ways of entering the professions.

The whole programme of the Assembly of Corresponding Societies at Liverpool was well designed to test and to explore these suggestions. Dr. P. M. Butler's paper on trends in natural history in the north-west of England was concerned with the new functions of the local scientific societies and with the ways in which they could to-day best help the amateur naturalists who are carrying on the work of those earlier naturalists of Lancashire, mainly botanists, and particularly around Manchester and Oldham, who in the first half of the nineteenth century had won an international reputation especially in the study of mosses. Mr. R. Wagstaffe, in speaking on "Natural History: the Amateur and the Professional", dealt principally with the functions of the museums, but indicated the extent to which the natural history departments of museums rely on the help of amateurs in securing material. The co-operation between amateur and professional, for which he pleaded, indicates one line of work which could be very fruitfully followed by the Assembly and its constituent societies.

That also applies to the question of publication, to which Mr. Wagstaffe referred very briefly, noting the difficulty which the small societies experience in financing the publication of their research results. The museum botanist and the community was the subject of a further paper by Mr. H. Stansfield. It is thus clear that this year's Assembly made a fair start on the consideration of how it and its constituent societies can best help those anxious to pursue science for its own sake and also foster a wider interest in and understanding of plant and animal life by the community. Two sessions were given to the consideration of practical problems of animal health and welfare and the protection of Nature, in which also public understanding is both desirable and often an essential condition for a satisfactory solution.

The session devoted to the presentation of science was, however, much more closely concerned with Dr. Swinton's suggestions and with the theme of Sir Edward Appleton's presidential address, as well as with the comments which he made at the close of the Liverpool meetings, when he stressed the importance of using simple language and ordinary words in public exposition. Dr. D. A. Allan was concerned with the museum presentation of science and the possibilities which such techniques afford of presenting scientific material and the development of scientific ideas. He recognized the tendency of museums to divide science into water-tight compartments, but the functions of the museum in adult or self-education are limited by the standard of public education and especially by the quality of the teaching of science in schools.

Mr. E. Yerbury's paper dealing with this topic was undoubtedly the key paper in this discussion. He thinks that in the schools science should be presented more as a means of service to the community, as a way of finding things out. It should be presented as an activity demanding discipline; for the child under fourteen, breadth rather than depth is important, and the content of science teaching should be related to the child's environment. For this reason he suggested that biology and general science, rather than the physical sciences, should form the approach and main content in school science. Referring to the shortage of science teachers, he stressed the importance of a sympathetic public, especially if science teachers of high character as well as ability are to be attracted.

Mr. Yerbury's address went to the root of the matter and indicated some ways in which the Assembly of Corresponding Societies can help to improve the situation. His constructive address contrasted sharply with the somewhat provocative address on the presentation of science to the public from Mr. Ritchie Calder which followed. Much of Mr. Calder's criticism of scientists as expositors, such as their failure to break through their own special or professional jargon when attempting to communicate ideas, their indifference to expressing themselves intelligibly, and their irresponsible refusal to consider and explain how their work affects the lives of ordinary people at a time when science is producing convulsive changes and dangerous stresses in our civilization, is merited by many. Scientists, however, are not the only ones who can be indicted as illiterate, inarticulate and irresponsible; very similar charges could be brought against journalists, for example, and so talented an expositor as Mr. Calder was obviously overstating his case when he argued that mass appeal and the box office returns should be the sole and final arbiter in the presentation of science.

To accept that view is to accept defeat. The terms of public exposition may well be set, as Mr. Ritchie Calder argued, by the nature of the mass mind or popular understanding. Neither the mass mind, nor popular understanding, is to be accepted as unchangeable, nor have they been accepted as such by the British Broadcasting Corporation, for example. The real task undoubtedly lies in the teaching of science in the schools, and from this point of view, as well as from that of the supply of scientists themselves, the shortage of science teachers is a problem to be tackled with the utmost energy and dispatch.

If, however, the presentation of science through the press, radio, television and the cinema is to be governed by quite low standards, as Mr. Calder suggested, even the best science teaching in the schools will fail to provide us with a public which really understands the possibilities of science, the implications of scientific advances, or, still less, is interested in science for its own sake. The presentation of science must be governed by some ideals and standards above those of financial return.

None the less, Mr. Calder gave another important reason why the scientist must himself take much more seriously the task of public exposition and interpretation. The steadily growing dependence of research upon public funds means that the public has a right to some clear understanding of what is being done with the large sums of money now voted for such purposes. Unless scientists take some trouble to explain the reason for such research and explain its progress, they are not entitled to complain if funds are withheld or curtailed; and if national interests are thereby injured, perhaps irretrievably, the real responsibility lies on the scientist who has failed to explain the situation clearly and firmly to the nation.

Mr. Calder, like Dr. Swinton, looked to the continuous popular exposition of science. The British Association should not, he thinks, limit its activities to its annual meeting, though he is thinking in terms of the press, radio, television and cinema, rather than the local societies. The Association has obviously been challenged at Liverpool, even more clearly than at Belfast or Edinburgh, to address itself as a whole to the task to which the Division for Social and International Relations of Science was dedicated on its formation in 1938. That the Assembly of Corresponding Societies has a large part to play is clear, though some further inquiry may be required to indicate more specifically the best lines of work either for the Assembly or for its constituent units. Meanwhile, the Sections of the Association are equally called upon to reconsider their functions in the light of the criticisms voiced at Liverpool and since. Nor is it too much to hope that scientific societies generally and professional associations of men of science will be stimulated to consider anew their functions in the world of to-day, not merely in regard to the presentation of science, but also to the advance of science itself, alike through the growth of popular understanding and through more effective co-operation between the professional and those others who pursue or seek to pursue science for its own sake.

ROLE OF PLASMAGENES

Nucleo-cytoplasmic Relations in Micro-organisms

Their Bearing on Cell Heredity and Differentiation. By Prof. Boris Ephrussi. (The William Withering Memorial Lectures delivered at The Birmingham Medical School, 1952.) Pp. viii+127+5 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1953.) 18s. net.

PROF. EPHRUSSI'S short book is based on three lectures given in the Birmingham Medical School last year. They contain very useful summaries of some of the recent work on cytoplasmic inheritance in lower organisms, particularly of his own studies on respiratory enzymes in yeast, together with those of Sonneborn, Beale and others on *Paramecium*, and the less well-known investigations of Rizet on the barrage phenomenon in the mould *Podospora*. The experimental evidence and the conclusions to be drawn from it are clearly and succinctly presented and form a valuable introduction to the literature. Unfortunately the diagrams, although at first glance appearing clear-cut and simple, are quite inadequately explained and in some cases I have still failed to understand what they are intended to convey.

Ephrussi discusses at some length the bearing of the facts he describes on the fashionable but somewhat nebulous idea that the discovery of 'plasmagenes' goes far towards revealing the fundamental mechanisms of differentiation in multicellular animals. In recent years this notion has been responsible for much muddled thinking, and at least in the first part of his book Ephrussi is not immune from this, although towards the end of it he does something to straighten matters out again. He starts, for example, by quoting a sentence from Darwin: "Inheritance must be looked at as merely a form of growth". But he promptly proceeds to reverse this, erecting a concept of "cell heredity" in which the more general phenomenon of growth, which usually leads to the subdivision of the growing mass by cell division, is considered as secondary to the more specialized phenomenon of heredity. This concept, which several authors have used, almost inevitably leads to attempts to draw parallels between two quite different processes; on one hand, the passing on of cytoplasmic constituents (plasmagenes), which are distributed from a cell to its daughters merely because the original cell is cut in half, and on the other the transmission of nuclear genes through the elaborate mechanism of gamete formation and fertilization. A property of genetic continuity is attributed to both nuclear genes and plasmagenes, but the evidence for it is of quite different, in fact almost opposite, nature in the two cases. Nuclear genes are considered to exhibit genetic continuity because they continue in existence throughout lengthy series of crosses, etc., whereas the evidence for the continuity of plasmagenes is the fact that if they are got rid of they cannot be regenerated.

Attempts to bring plasmagenes into play to explain differentiation also lead to confusions. The phenomenon to be explained is the arising of new and diverse types of tissue. If the immediate cause of the appearance of a tissue is the occurrence of the appropriate plasmagene, we have two possibilities. Either the plasmagenes arise *de novo* during development, in which case they are doing exactly that thing the impossibility of which is used as a means of detecting them; or they are all present, possibly in an inactive form, in the unfertilized egg, in which case they are nothing but our old and discredited friends the 'organ-forming substances' appearing under a new name and with their hair curled in the latest fashion.

The true importance of the plasmagene work for the study of development would seem to be that it has brought home to geneticists a fact long realized by embryologists and cell physiologists, namely, that the cytoplasm is not a mere sackful of small-molecular products thrown out by the genes, but contains particles of at least the same order of size and complexity as the genes themselves, though it seems that only very rarely in higher animals can these particles take the lead in cell functioning.

Ephrussi seems to be gradually approaching some such position as this. True, he starts off on the wrong foot, arguing rightly enough (on p. 4) that development involves a "differential [which] must have its seat in the cytoplasm", but drawing the complete *non sequitur* that "if the cytoplasm causes differentiation it must be endowed with the power of perpetuation of cell-type". But by pp. 105–6 he has come to the more convincing opinion that "the cell is an integrated unit which can be broken down only for purposes of analysis" and "we may therefore speak of autoreproduction of the integrated unit which is the cell, but it would be more correct not to speak of autoreproducing particles". The journey from the earlier view to the later not only exhibits a fascinating panorama of facts, but also is of the greatest intellectual interest and stimulus. Ephrussi's book should certainly be read and deeply pondered by all who are interested in the fundamental questions of biology. C. H. WADDINGTON

EXPERIMENTAL DESIGN IN BIOLOGY

The Design and Analysis of Experiment
By M. H. Quenouille. Pp. xiii+356. (London: Charles Griffin and Co., Ltd., 1953.) 36s. net.

THIS book, according to the author's preface, "is aimed at those wishing to acquire a working knowledge of experimental design and an understanding of the principles governing it". The subject is approached from the point of view of biological experimentation, and all the examples are drawn from this field. The book is designed for readers with a comparatively slight mathematical background, and the results are for the most part presented without proof. It is divided into four sections: elementary principles and designs; incomplete block designs; long-term policy; and experimental complications.

The reader is assumed to possess some knowledge of statistical method up to analysis of variance and regression, and also of the basic principles of experimentation; these topics are summed up in a somewhat indigestible first chapter. The remainder of the first two sections is devoted to the more familiar experimental designs, the account of the construction and analysis of each type of design being generally followed by a clearly worked example. These examples are drawn from a wide range of biological experiments—they are discussed in some detail and are well chosen to illustrate the suitability of the particular designs used.

In the third section, the planning and analysis of groups of experiments are discussed. In particular, detailed consideration is given to methods of design and analysis for estimating residual effects of treatments, and to the combination of results from experiments with differing precision. The topics of this section have been comparatively neglected, and many of the methods described should prove useful both to statisticians concerned with planning groups of experiments, and to the experimenters themselves, although the treatment requires more familiarity with statistical techniques than most experimenters may possess. This is perhaps also true of the fourth section, in which, among other things, are discussed a number of special designs which may be required in peculiar circumstances (for example, $p \times p$ factorial designs with missing diagonals), and the transformation of experimental observations. These sections are useful in collecting together the results of researches which have been carried out in various fields in recent years. There is an extensive and useful bibliography with many references to both theoretical and practical sources.

The author has, perhaps, tried to include too many topics in one volume. This results in the first half containing insufficient detail for those entirely new to experimental design, while in the latter half are included some sections (such as that on sequential analysis) in which the treatment is too brief to be of much value. It is difficult to recommend this book whole-heartedly to experimenters or to statisticians; however, it contains material which should be interesting and useful to both groups.

INTERPRETATION OF NUCLEAR DATA

Theoretical Nuclear Physics
By Prof. John M. Blatt and Prof. Victor F. Weisskopf. Pp. xiv+864. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 100s. net.

PROFS. BLATT AND WEISSKOPF have written an excellent account of the present interpretation of nuclear data, and their book will doubtless become a standard work. Nevertheless, it does not pretend to contain a complete nuclear theory: in addition to the inevitable complexity of the many-body problem we still do not know the elementary law of force between nuclear particles or how the forces between individual particles add up, and some physicists doubt whether the concept of a potential energy between nucleons is valid. In this situation it is a merit of the book that much of the discussion is in terms of general concepts rather than of special models. For example, in the two-body problem considerable use is made of the theory of 'effective range' which does not need to assume any specific shape for the potential between nucleons.

Three chapters, totalling about 250 pages, are devoted to nuclear reactions, mainly to the discussion of the dispersion formula. Some powerful theorems on angular distributions and correlations are included. Chapter 10, on the formal theory of nuclear reactions, also contains a clear account of the relationship between the principles of reciprocity and detailed balance for the transitions of a quantum mechanical system; a matter which has often been confused in the literature through undue reliance on simple perturbation theory. These chapters will be very useful to the experimental worker, though Chapter 8 makes heavy reading. Together with so much general theory it would have been helpful to include a simple explicit example of how analysis of angular distributions can lead to assignment of spins and parities.

An indication of the experimental progress of recent years is that Profs. Blatt and Weisskopf, unlike most previous authors, make no attempt to include a table of nuclear species and their elementary properties; this task now occupies a special publication of telephone directory dimensions. The shell model of low-lying nuclear states, which represents the consequent theoretical progress, is treated in the last chapter of the book. It is a pity that this model was not available to the authors when the earlier chapters on nuclear spectroscopy were written, as a few apparent inconsistencies with the last chapter might have been avoided.

The authors wisely avoid meson theory, so the text can be read by anyone who understands simple quantum mechanics; even the relativistic Dirac equation appears only in connexion with the theory of β-decay. K. J. LE COUTEUR

MAGNETIC PROPERTIES OF THE EARTH'S INTERIOR

THE renewed interest in attempts to explain just why the earth has a magnetic field, and the feeling of optimism that at last this long-standing riddle of geophysics may soon be solved, were reflected in the contributions to the discussion on the magnetic properties of the earth's interior held on September 4 by Section A (Mathematics and Physics) of the British Association at its Liverpool meeting.

The discussion was opened by Sir Edward Bullard (National Physical Laboratory, Teddington), whose recent contributions to the dynamo theories of the main field and of its secular variation have been mainly responsible for the great revival of interest in this problem. In a most illuminating and entertaining introduction, Sir Edward reminded his audience of some of the important features of the field that call for explanation. The fact that the field resembles that of a uniformly magnetized sphere —that is, a dipole field—was established as early as 1600 by William Gilbert. During the past hundred and twenty years, however, the magnetic moment of this dipole field has decreased by as much as 4·5 per cent, a very remarkable rate of change for any planetary phenomenon. If this were to continue, there would soon be no field left to investigate! "However, I am happy to announce," continued Sir Edward, "that this contingency will probably be avoided, since there is now evidence that the moment reached a minimum about 1935, and appears now to be increasing again."

When the main dipole field is removed, the residual field is one of considerable complexity. A chart of this field is not unlike a meteorological chart in appearance. The resemblance is even closer when one remembers that both charts will change with time, the secular changes in the geomagnetic field during, say, a century being of the same order as those occurring on a weather map during a week. The comparison is perhaps not entirely fanciful and tends to suggest that the geomagnetic phenomena may originate, like the weather changes, from causes associated with fluid motions. Another specially significant feature of the geomagnetic field is the observed westward drift by about 0·2° longitude a year of the general pattern of the secular variation field, this drift being superposed on the general waxing and waning of the individual foci of change.

Sir Edward then reviewed the many and varied explanations, including some that he frankly labelled "magic", which have been put forward to account for the existence of the magnetic field. In view, however, of the features already mentioned and having regard to the reasonable assumptions we can make about the properties of the earth's interior, the only kind of explanation likely to be satisfactory is one which involves the production and maintenance of electric currents flowing mainly in the liquid core. The radius of this core is known with considerable exactness from seismological studies, and there are good reasons for believing that it has a metallic conductivity. The electric currents might be produced by chemical action, or by thermoelectric or dynamo effects. No precise mechanism involving chemical effects appears to have been considered, but mechanisms involving thermoelectric and dynamo effects have both been discussed in some detail.

The possible existence and effectiveness of thermoelectric couples at the interface between the metallic core and the silicate mantle have been considered by Dr. S. K. Runcorn at Cambridge, who has suggested that, if temperature differences caused by heat convection exist on the surface of the core, electric currents will be set up flowing partly in the core and partly in the mantle. Since the thermoelectric e.m.f.'s are radial, the resulting magnetic field would not be the dipole field actually observed, but further interactions with fluid motions in the conducting core could lead to this field. Sir Edward considered, however, that the temperature differences on the surface of the core which are required in this theory are so great that they would imply an unlikely large heat convection within the core.

In the dynamo theory, as developed mainly by Prof. W. M. Elsasser in the United States and by Sir Edward in Great Britain, the electric currents are generated through electromagnetic induction by the interaction of fluid motions in the core with the internal magnetic field of the currents themselves, the whole system forming a self-exciting dynamo which obtains its energy from the heat generated by radioactive material in the core. A heat generation of a few per cent of that occurring in surface rocks would suffice to maintain a convective motion with material rising at some places and sinking at others. The radial component of this convective motion will be affected by the earth's rotation and will lead to a radial gradient of angular velocity of the fluid, the outer part of the core rotating more slowly than the inner part. Since a highly conducting fluid will tend to carry any magnetic field along with it, this retardation of the outer part of the core may be the cause of the westerly drift of the secular variation field. The convective streaming in the fluid core together with the differential rotation might, in the presence of some small initial magnetic field, build up and maintain the field at some definite level; in other words, the core would behave as a self-exciting dynamo. To prove rigorously that this is possible, it is necessary to show that Maxwell's equations for a moving fluid possess solutions of the necessary type. This analytical problem has been studied by Sir Edward, and he believes that it will be feasible to establish the possible existence of such a dynamo. The analysis is, however, extremely complex, as the large gathering fully appreciated when some of the equations involved were shown on the screen.

Prof. A. T. Price (University College, Exeter) then described how the study of short-period fluctuations of the geomagnetic field can yield information about the distribution of electrical conductivity within the earth. Though this information is rather limited, due account must be taken of it when seeking to explain some of the features of the geomagnetic field, especially the secular variation. Several types of fluctuation have been studied; but most work has been done on the daily variations and the storm-time variations. Both these are primarily of external origin, being due to varying electric currents in the ionosphere; but these ionospheric currents induce other currents within the earth, and a comparison of the magnetic fields of the inducing and induced currents can tell us something about the electrical conductivity of the region where the induced currents flow.

The calculations which have so far been made indicate a considerable rise of conductivity with increasing depth within the earth, from about 10^{-14} e.m.u. or less for dry surface rocks to a value of at least 10^{-11} e.m.u. at about 900 km. depth. No direct information about greater depths can be obtained from the magnetic variations, because the corresponding induced currents do not penetrate appreciably farther than this. If, however, the observed rise of conductivity can be accounted for on some reasonable hypothesis based on known physical laws, it may be possible to extrapolate the results to greater depths with some degree of confidence, and this has in fact been done. A very reasonable supposition is that the increase of conductivity is associated with the increase of temperature as one goes downwards in the earth. The material of the earth's mantle is probably some form of olivine, and is in any event almost certainly a semi-conductor, in which the conductivity σ at high temperatures will be a function of the temperature T of the form $\sigma = \sigma_0 \exp(-A/kT)$. The coefficients σ_0 and A may depend somewhat on pressure and temperature; but the important changes in σ will be due to the exponential factor.

Laboratory measurements of the conductivity of various olivines at temperatures up to 1,500° C. have recently been made by H. Hughes at Cambridge, following some earlier work done there by H. P. Coster. These experiments reveal a very great increase of σ with temperature, and it appears that most of the materials examined behave like ionic semi-conductors at sufficiently high temperatures. From his results Hughes has determined the relevant values of σ_0 and A. He has also obtained corresponding values of these coefficients for the earth's mantle by comparing the distribution of conductivity, as derived from the geomagnetic data, with recent estimates of the distribution of temperature within the earth. The values he obtains, $\sigma_0 = 2 \times 10^{-3}$ e.m.u. and $A = 3 \cdot 5$ eV., are of the same orders of magnitude as those derived from his laboratory studies. He has therefore used the above formula to extrapolate for σ throughout the mantle, and thus obtains an estimated value of about 3×10^{-6} e.m.u. near the base where it meets the liquid core. This is somewhat higher than earlier estimates. One consequence of a higher conductivity of the mantle would be a tighter electromagnetic coupling between the mantle and the core, and this seems likely to remove one of the difficulties which appeared hitherto in the explanation put forward by Vestine, and by Munk and Revelle, to account for certain sporadic variations in the length of the day, which appear to be associated with variations in the rate of westward drift of the secular variation field.

Another important aspect of the geomagnetic field was discussed by Mr. J. Hospers (University of Cambridge), who described geological evidence which indicates the occurrence of repeated reversals of the main field. He gave an account of work recently done on the natural permanent magnetization of lava flows and sediments found in Iceland. The historic flows of Mt. Hekla, 1766–1948, are magnetized approximately in the direction of the present local geomagnetic field, and their magnetism has undoubtedly been acquired through cooling in the existing field. For the post-glacial lava flows, about 2,000–6,000 years old, the angle of mean direction of magnetism with that of the present field is 7·5°, and with that of the dipole field is 2·5°. This suggests that over a period of some thousands of years the magnetic pole has been centred on the geographic pole. Early Quaternary flows show, however, a reverse magnetization, and Tertiary flows show alternating series of normal and reverse magnetizations. T. Nagata, in Japan, has shown that certain specimens of pumice from Mt. Haruna can acquire a reverse magnetization on cooling in a magnetic field; but no similar effects have been found for any of the Icelandic lavas. The observations, therefore, indicate that repeated reversals of the local magnetic field have taken place; moreover, since the changes have all corresponded to the field swinging right through 180° without intermediate directions being in evidence, it seems probable that the reversals of the field are in fact world-wide. This implies that the main geomagnetic field can reverse its direction every 2×10^5–5×10^5 years, and that this has been happening at least since Miocene times—that is, for the past 20×10^6 years.

The mean direction of magnetization of the Tertiary flows is very close to the direction of the present dipole field. This suggests that, unless the magnetic axis has departed appreciably from the rotation axis, which seems unlikely from the foregoing evidence, there have been no appreciable changes in latitude or orientation of Iceland during the past 20×10^6 years. Some further work on Eocene flows in Northern Ireland, which are about 50×10^6 years old, indicate that, if any polar wandering occurred during Tertiary times, it was much less than has sometimes been supposed.

In the final paper to the symposium, Dr. F. J. Lowes (University of Liverpool) discussed the possibility of attributing the earth's magnetic field to currents produced by thermoelectric effects at the interface between the core and mantle, and examined the implications of this hypothesis. The existence of a considerable voltage distribution is required on the surface of the core, and this in turn requires considerable temperature differences, which are assumed to be produced by the convective motions within the core. The resulting currents would, however, flow in the mantle as well as in the core, in contrast with the situation in the dynamo theory, where the most intense currents flow well within the core. There is, moreover, a difficulty in the dynamo theory in that the changing currents which give rise to the secular variation must flow, owing to the skin effect, within 10–100 km. of the surface of the core, whereas the liquid eddies required to produce these currents would have radii of about 500 km. In the thermoelectric theory this difficulty is avoided because changes in the voltage distribution would directly affect the currents flowing in the mantle, and lead to the observed changes in the magnetic field. The thermo-electric theory also seems to fit in better with recent explanations given for sporadic changes in the length of the day. These are thought to be due to transfers of momentum between mantle and core, the necessary torques being of electromagnetic origin. This requires magnetic fields of order 10–100 gauss in the lower part of the mantle, a condition which is probably more easily met in the thermoelectric than in the dynamo theory. It must, however, be admitted that the difficulty of providing sufficiently effective thermoelectric forces at the core–mantle boundary still remains.

A. T. PRICE

PROGRESS OF CANCER RESEARCH

THE thirtieth annual report of the British Empire Cancer Campaign for 1952 is a formidable volume of 400 pages (from the Campaign, 11 Grosvenor Crescent, London, W.1). Only a few of the many lines of investigation described in the report can be discussed in this review.

The part played by smoking in the causation of lung cancer is probably the outstanding question of popular interest in cancer research to-day. Lung cancer has increased ten times (some authorities say eighteen times) in less than thirty years, and is well on the way to becoming the most common form of neoplasia in the male. The difference in sex incidence of the disease, the spraying of tobacco crops with insecticide containing arsenic, and the immense number of cigarettes consumed nowadays have all suggested that cigarette smoking might be a factor in lung cancer. Statistical analysis has, in fact, shown this to be the case (Table 1[1]).

Table 1. CIGARETTE SMOKING AND LUNG CANCER
Of 1,000 men aged twenty-five, the following numbers can be expected to die before the stated age

Age (years)	Non-smokers			Smoking 15–25 cigarettes per day			Smoking 25–50 cigarettes per day		
	From cancer of lung	From other causes	From all causes	From cancer of lung	From other causes	From all causes	From cancer of lung	From other causes	From all causes
55	1	130	131	15	128	143	22	127	149
65	2	298	300	32	292	324	54	288	342
75	3	577	580	52	557	609	90	541	631

The opponents of the 'cigarette theory' could point out that while the consumption of tobacco per head has only increased from 9·1 lb. per annum in 1921 to 9·6 lb. in 1951, the incidence of lung cancer has multiplied ten times in that period; that in Turkey, where the tobacco contains vanishingly small amounts of arsenic, lung cancer is almost as frequent as it is in Britain; that the great increase of the disease might be attributed to mounting atmospheric pollution due to the enormous rise in the use of the internal combustion engine (petrol and diesel); that in Iceland, where industrialization has scarcely begun, lung cancer is uncommon; that Stocks's important work has proved that the incidence of lung cancer in urban districts is roughly proportional to the density of the population.

To all of this the answers would be: see Table 1; that cigarette smoking as against pipe smoking is a comparatively recent custom; that no one would attribute lung cancer solely to cigarette smoking, which can be regarded as a synergistic factor to atmospheric pollution just as sunlight and genetic factors are synergistic for cancer of the human epidermis (xeroderma pigmentosum), chemical carcinogens and genetic factors are synergistic for lung and liver cancer in the mouse, carcinogens and the Shope virus for skin cancer in the rabbit, and carcinogens and Bittner virus for mammary cancer in the mouse[2].

The report gives an account of investigations on the effect of cross-breeding on tumour induction which are of extraordinary interest. Pybus and Miller have been working on lines similar to those of Strong in the United States, who injected mice with a single dose of carcinogen (methylcholanthrene), and had found that the untreated descendants of these mice were particularly liable to stomach tumours without the necessity for any further injection with carcinogen.

The effect of crossing two inbred lines of mice (female lung cancer-rates 7·5 and 1·6 per cent) was to increase the lung adenoma rate in the hybrids; but reciprocal crossing had the strange effect of almost doubling the lung tumour-rate: 20 per cent of the females developed lung tumours as compared with 9 per cent in the reciprocal cross. Methylcholanthrene increased the incidence still further to 31 per cent. "In the uninjected descendants of injected mice the lung tumour incidence was less than in the control hybrids; this suggests that the methylcholanthrene acted directly on the lung tissues and that there was no genetical effect." The mice were injected once only at 60 days of age; the lung tumours appeared in 9·8–22·4 months in males and between 14·4 and 27·9 months in females.

The incidence of mammary carcinoma presents some puzzling features. Neither the inbred strains *NBT*, nor *CBA*, nor their descendants developed mammary cancer, but the crosses did; *NBT/CBA* hybrids (the maternal strain is given first) showed 3·8 per cent tumour bearers, the reciprocal cross (*CBA/NBT*) gave 1·6 per cent. These figures represent the average for twelve consecutive generations, for most of the mammary tumours appeared in the first two generations of hybrids where the incidences were 10·3 and 5·5 per cent in *NBT/CBA* hybrids and 5·2 and 4·1 per cent in *CBA/NBT* hybrids. "These figures suggest the presence of a weak maternal influence in the *NBT* mice but more than twice as potent as any corresponding influence in the *CBA*. The incidence dropped markedly in later generations, where only an occasional case occurred."

Dmochowski, in experiments on mouse mammary cancer induced by the milk factor, has found that, after strains of mice which are very seldom liable to this tumour have been inbred a number of times, a generation can appear which develops the disease and carries the transmissible milk factor; sometimes seven or even ten generations may have remained free from tumours and milk factor. Infection is not thought to be the responsible mechanism (as tests on close bodily contact between a milk-factor carrier and a factor-free mouse have demonstrated in experiments by Andervont *et al.*).

Does the virus-like milk factor arise *de novo*? The investigators engaged in this work show something like panic at the thought of such heresy. They say: "Without experimental facts it would be sheer speculation to suggest how it comes about that the milk factor is now detectable in this sub line". (However, one plant-virus authority believes that there exists some evidence of *de novo* appearance of virus in the potato[3].)

At Leeds, Bonser and colleagues have obtained some evidence in favour of the metabolite theory, which postulates that a carcinogen has first to be converted to its hydroxy derivative before carcinogenesis can proceed. β-Naphthylamine, while a potent carcinogen for human bladder epithelium (dye-workers' cancer), has been found to act exclusively in the dog and not in other experimental animals when it is administered by conventional methods such as in the diet. Bonser's technique consists in inserting wax pellets containing carcinogens surgically directly into the bladders of mice; it was found that 1 hydroxy-2-amino naphthol was carcinogenic, but that the amine itself was not. However, benzcarbazole *per se* was active.

The majority of the reports on strictly morbid anatomy are of the type—case reports, and collections of cases from the files of a department to illustrate some particular point—which constitutes the bread-and-butter of publication of any university pathological department. Save that most of the items deal more or less directly with cancer of some sort, one can find little evidence that the work of the pathologists supported by the Campaign differs in any way from that of their colleagues in general.

There would seem to be three types of project in this field in which the support of such a body as the Campaign could be of decisive importance. The first is the massive co-operative effort, typified by Dr. W. L. Harnett's "Survey of Cancer in London" (reviewed in *Nature*, 170, 220; 1952); no scheme of equal scope seems to be under way at the present. The second is the prosecution of research overseas, in areas where pathological facilities are inadequate, into the tumours characteristic of those regions, and the elucidation of which is often of the greatest value for the study of tumours in general. There is no suggestion of such work in the present report. An investigation into the carcinogenicity of *Acacia arabica* by Dr. R. Schoental, derived from observations by Dr. V. R. Khanolkar on the frequency of glottal and tonsillar cancer in Gujrati Indians who use acacia twigs as toothbrushes, and continuation of the same investigator's work on *Senecio* liver tumours, is the only reference to the incidence of cancer in non-white races. The third type of project is the long-term study of a single group of tumours in all possible aspects, at a single institution, by standardized methods, and so far as possible by the same people throughout. Of this type the report mentions one old, honoured and outstandingly successful example, and several hopeful juniors.

The major example referred to is, of course, the investigation at St. Mark's Hospital, under Dr. Cuthbert Dukes, into tumours of the colon and rectum, which must now be approaching the end of its third decade. Dr. Dukes's series of cases of familial intestinal polyposis now includes 41 families, with 753 members, among whom there have been 156 cases of polyposis: much valuable information arises from their study. Studies of the malignant rectal polyp and of the large villous tumour of the rectum are also presented. Individually these appear pedestrian in the extreme; but that is characteristic of this kind of investigation: much of it is what Dr. Dukes himself has described as "the luxury of proving what we already know to be true". But over the years a body of exact and unique information has been built up, more, probably, than is available for any other group of tumours in the body.

It may serve as a useful cross-section of the pathological material contained in this report to give a résumé of work on one single aspect, cancer of the lung. These are all the relevant articles found: (*a*) the joint clinical-therapeutic study shared between the Cancer Hospital and the Brompton Hospital; (*b*) a study of pneumonectomy specimens in progress at the Middlesex Hospital; (*c*) a search for carcinogens in cigarette ends, by chemical means, at the London Hospital; (*d*) investigations by Sir Ernest Kennaway into the carbon content of human lungs, into the incidence in coal miners, and into the curious relationship between the incidence of cancer of the lung and the larynx in various districts of England and Wales; (*e*) experimental studies at Leeds; these last have had as their main result to date the observation that a potent carcinogen absorbed on carbon, inhaled as dust and retained in the lung, will not produce lung tumours in mice; suggesting that direct animal experiment will not give a simple answer to any problems connected with the carcinogenicity of, for example, cigarette smoke. The difficulty here is very similar to that emphasized by work on carcinoma of the stomach at Leeds, also described in the report, where again known carcinogens have failed to produce tumours in what appeared to be the most favourable possible circumstances. Whether the answer is one of species difference, of the activity of a carcinogen not recognizable as such in standard animal experiments, or of the absence of any external carcinogen, the fact remains that the experimental study of these two tumours, so common and important in man, has not yet borne any fruit at all, and that the study of human material remains for the present the only profitable line of attack.

In the field of physics this report shows that work continues to cover an ever-widening field, and that the problems studied have a very wide variety of starting points, ranging from the investigation of the structure of proteins to measurements on a 1,000-C. cobalt-60 source. The problems connected with the production and measurement of megavoltage radiation are being studied at a number of centres. Various methods of production of such radiations are now in routine use and a wide variety of protection problems arise as a result. The contamination due to radioactive dust arising from the use of cobalt-60 sources has been reported and various methods suggested for overcoming this complication. The absorption of high-energy radiation in a selection of high-density liquids has been studied with the aim of designing a transparent window through which patients can be observed while undergoing treatment; solutions of lead perchlorate were found to give encouraging results.

Scintillation counting appears to be receiving widespread notice and its applications are becoming increasingly varied. The photomultiplier system used with these counters has now been applied to the measurement of 'chemi-luminescence'—the light emission which may accompany chemical reactions; while scintillation dosimeters of very small dimensions suitable for the measurement of dosage-rates in body cavities or around interstitial implants are also reported.

The main advances in the use of radioactive isotopes seem to be in the investigational and diagnostic field rather than in therapy, though improvements in existing therapeutic techniques have been achieved. Side by side with these technical advances, work continues upon the development of reliable methods for the standardization of measurements of the radiations emitted from the many different isotopes used in the medical field. The use of iron-59 for the study of blood conditions in malignant disease and as an indication of the total whole-body irradiation received during treatment with ionizing radiations is being given careful attention. The uptake of sulphur-35 in bone marrow and the localization of phosphorus-32 within the cell are being studied with improved techniques of autoradiography.

The study of protective agents during irradiation is widespread, and varies from the shielding of certain specific parts of an animal being irradiated and the use of 'sieves' during therapy, to the administration of chemical agents prior to irradiation. The effect in bone due to irradiation by 220-kV. and 2-MeV. beams and also the relative loss of phosphatase in mouse bone after irradiation by beams of energy varying from 100 to 1,000 kV. offer interesting evidence of the biological response to such radiations.

NEW FISHERIES LABORATORY, BURNHAM-ON-CROUCH

By Dr. H. A. COLE

A NEW Laboratory for research on inshore and shellfish problems was formally inaugurated at Burnham-on-Crouch, Essex, on September 23 by Mr. G. R. H. Nugent, M.P., joint parliamentary secretary to the Ministry of Agriculture and Fisheries, at a large gathering of representatives of local authorities in Essex, the sea fisheries committees of England and Wales, the shellfish industry and the universities and marine laboratories. Mr. Nugent was introduced by Mr. Michael Graham, director of fisheries investigations; Mr. E. R. Chadwyck-Healey, prime warden of the Fishmongers Company, and Mr. T. Driberg, M.P. for Maldon, also spoke.

The Laboratory is intended to serve as a centre for the wider investigation of inshore and shellfish problems than has hitherto been possible in the somewhat restricted accommodation provided by the Fisheries Experiment Station, Conway. Work will continue at Conway with a reduced staff on certain problems, notably the selective breeding of oysters and the cleansing of shellfish, for which the station is especially equipped.

The staff at Burnham comprises six scientists with technical and clerical assistance. The Laboratory is equipped with two research vessels. The larger, *Wysirys*, a converted oyster smack built at Whitstable nearly thirty years ago, saw war service with the Sunderland pilots. She is 50 ft. overall and is equipped with a specially designed trawling gallows from which two 4 ft. 6 in. dredges can be worked. The smaller vessel, *Jasea*, was recently built at Leigh-on-Sea and, although only 32 ft. in length, also works two large dredges. She has been designed as a general-purpose vessel for shrimp trawling, dredging and general research work.

The Laboratory has also been provided with about a hundred acres of experimental oyster grounds in the Rivers Crouch, Roach and Blackwater, some of which have been purchased while others are leased. Many were derelict when taken over and the principle of the reclamation methods is to introduce mechanized cultivation at stages discovered by biological research to be critical, bearing in mind the economic factors. The work is providing new information on the control of pests and on the factors affecting the productivity of oyster grounds.

Fig. 1. The new Fisheries Laboratory of the Ministry of Agriculture and Fisheries at Burnham-on-Crouch, Essex

The Burnham Laboratory has been designed along simple functional lines with a preparation room, six research laboratories, a general laboratory, tank room, library, dark room, workshop, stores and offices, all on one floor, with a central corridor running the full length of the building. The construction is brick on a reinforced concrete secular raft, with a flat roof.

The site is immediately inside the sea-wall at the eastern end of the river front, and the Laboratory faces north-west on to open country. Sea water is delivered by special electrical pumps with hardened rubber casings into two cast-iron storage tanks on the roof of the Laboratory, from which discharge is by gravity to six small concrete tanks and a double row of sinks in the laboratory tank room. The larger piping is in cast-iron with an inert inner coating; the smaller piping is in ebonite. There is no recirculation of water, which is discharged to waste. Pumping arrangements are to a large extent automatic; but special provision has been made for flushing silt from the intake mains, as in the River Crouch the water is often very turbid. Compressed air is provided in all laboratories and in the tank room.

This is the first laboratory specially built for fishery research in the United Kingdom during the seventy or so years since its inception. The Crouch–Roach river system and the Thames area provide facilities for research on many inshore and shellfish problems. In addition to the important oyster fisheries in the Rivers Colne, Blackwater, Crouch and Roach, and at Whitstable, there are large shrimp fisheries based on Leigh-on-Sea, Tollesbury, Harwich and other ports; one of the largest cockle fisheries in Britain is based on Leigh-on-Sea, with many communities of inshore fishermen between Harwich and the North Foreland. The vast shellfish beds in the Wash, the most important in point of yield in England and Wales, are within easy reach. Rail access to London is good, and it is hoped that the presence of a fully equipped marine station in this area will be taken advantage of by members of universities, for whom there is a certain amount of laboratory space.

Work was begun at Burnham-on-Crouch in 1947 in temporary quarters, and attention was concentrated first on the difficulties of the East Coast oyster industry, the productivity of which was at a low ebb, following the effects of the War and the exceptionally severe winters of 1940 and 1947, which aggravated a situation already difficult following the spread and multiplication of two imported oyster pests, the American slipper limpet, *Crepidula fornicata*, and the American whelk tingle, *Urosalpinx cinerea*. The research programme will gradually be expanded to include the study from the fishery aspect of all species of molluscs and crustacea of commercial importance; the economics of the inshore fishing industry will require examination at the same time. Current research work at the new Laboratory includes an investigation of the causes of fluctuations in the annual production of seed oysters in Essex; the control of oyster pests; an examination of the losses resulting from the relaying of oysters; the causes of the fluctuations in the pink shrimp fishery of the Thames area; the biology and control of the mussel parasite, *Mytilicola intestinalis*; the overfishing of cockle beds in South Wales; an examination of the fishery aspects of the 'white weed' industry (*Sertularia cupressina*); and a detailed study of the taxonomy and ecology of the small marine algæ which are of such importance as food for marine larvæ.

The inshore fauna of the rivers and creeks of the Essex coast has been little studied and has proved to be of great interest. In shallow water the benthic community is dominated by *Crepidula*, with, in some areas, vast quantities of ascidians, principally *Ascidiella aspersa* and *Ciona intestinalis*. Silt in suspension greatly affects the composition and distribution of the fauna, which is highly specialized, with close resemblances to the communities found in the Oosterschelde and the Wattenmeer, across the North Sea. Peculiar salinity conditions are also to be found in the rivers and creeks, which are in reality embanked inlets in the marshes. In the upper reaches in summer, salinity often exceeds 35 °/₀₀, and temperatures of more than 20° C. may occur for several weeks at a time. Interchange and mixing with the North Sea is very slight in summer as the rainfall is low. As a result of these peculiar hydrological conditions there exists in the creeks a strongly marked community of animals which differs markedly from that found on more open coasts north and south of the Thames Estuary.

THE SALDANHA SKULL AND ITS ASSOCIATIONS

By Prof. M. R. DRENNAN

University of Cape Town

THE expanding story of early man is a composite one, depending for its growth and documentation on the evidence from fossil remains and stone implements. It is in the nature of things that his stone implements should have survived the passage of time to a far greater extent than his bony remains. Only rarely, and often in unexpected places, do we get those fortuitous circumstances that lead to fossilization.

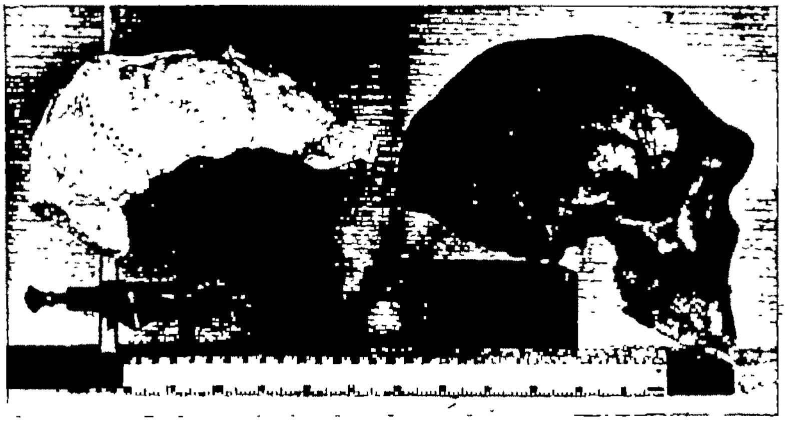
This is particularly true of that early stone-knapper, whom we call 'hand-axe man', because we know very little about him beyond the fact that he continued to make this implement to a more or less standardized pattern during the longest of human cultural spans, namely, the lower palæolithic.

In Europe the faunal remains of this period have survived to a considerable extent, and they reflect the cold and warm alternations of the Ice Ages. Human remains, however, are still very scarce, and at the moment are limited to two incomplete and apparently sapient human skulls, one from a Thames' terrace at Swanscombe, and the other from the Fontéchevade cave in France.

In South Africa, the hand-axe culture abounds in all the old river terraces; but for the most part the implements of this period are unaccompanied by bone. The one exception, so far, is the Vaal River, where the intensive search for diamonds has led to the discovery of valuable fossil remains.

The Site and Associated Fossils

In the Cape of Good Hope region, however, it is only within the past two years that the disparity between stone implements and fossils has begun to be redressed. This has been done by a group of scientific workers from the University of Cape Town, who have been studying a rich exposure of stone implements and fossils on a farm called 'Elandsfontein', owned by Mr. S. P. Lategan, and situated eighty miles



Side view of the Saldanha skull-cap and of a cast of the Rhodesian skull

due north of Cape Town. The fossiliferous area lies in the centre of a somewhat barren twenty-mile wide strip of sandy bush veld, bordering on the almost landlocked Saldanha Bay and Lagoon.

The exposures, which have been shown from a recent survey to extend over an area of several thousand acres, are the result of wind erosion, the south-east wind having scoured out troughs and valleys, winnowing out the fossils and stone implements, and driving the sand northwards in vast moving sand dunes.

The University committee responsible for the investigation of the site has been fortunate in having the services of Mr. J. A. Mabbutt, lecturer in geography, who was already studying the physical geography of the adjoining Berg River. His findings may be summarized as follows. The fossiliferous area is situated on a low sandy plateau, 300 ft. above sea-level, and the fossils and implements have obviously been derived from the erosion of old pan floor deposits and their flanking dunes. It would appear from a study of the sand that the fossils lie in a zone of contact between old coastal shelly sands stretching west to the Atlantic, and brown inland sand on the eastern, landward, side. Curious ridges of ferruginous sandstone (ferricrete) which abut on the limestone (calcrete) suggest an earlier higher water-table, possibly even a wetter period, with dammed-up vleis or ponds providing an attraction for the game and also for the hunters.

On a recent visit Mr. Mabbutt dug a trial pit on the main site, and he was successful in locating the original bedding layer of the fossils.

Mr. Keith Jolly, field officer for the work, has made an extensive collection of the stone implements and fossils. The former comprise a technological sequence of late Stellenbosch (Chelles-Acheul) hand-axes and a rich assemblage of pigmy hand-axes and cleavers suggesting the presence on the site of exponents of the Fauresmith (proto-Mousterian) industry of the northern provinces of South Africa. In addition, there are good examples of the bifaced points of the Still Bay industry of the later South African Middle Stone Age.

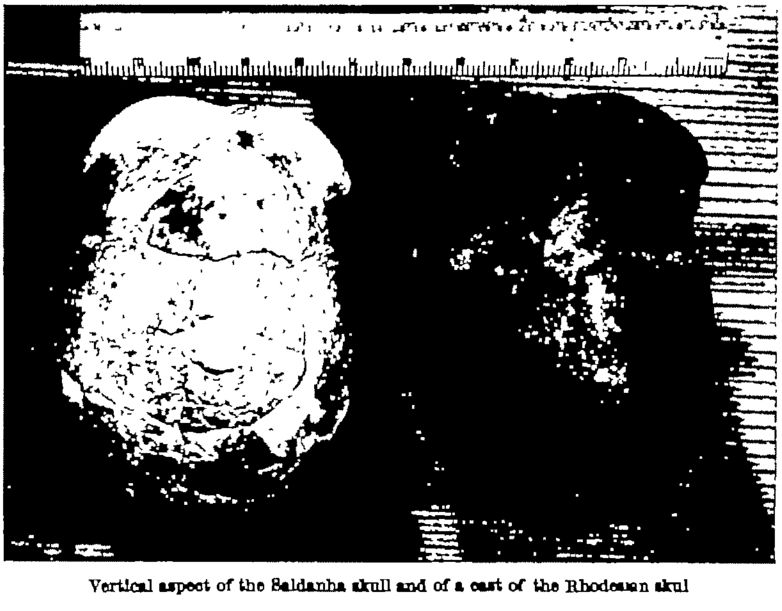
My two senior assistants, Dr. E. N. Keen and Dr. R. Singer, have studied the mammalian fossils which have so far been collected, and they have established the fact that a considerable proportion of the bones and teeth represent extinct types of African mammals. One of the most striking of these is the giant-horned buffalo, labelled tentatively *Homoiocerus bainii*. Another giant form that occurs is the warthog (*Mesochoerus*), which has teeth greatly exceeding in size those of any of the living forms of this animal. An archaic form which is well represented is the African mammoth (*Palaeoloxodon*), and there is one set of teeth of the rare primitive giraffe (*Griquatherium*).

The Equidæ are very numerous and in this respect the site seems almost to rival Solutré. In addition, there are many examples of the teeth and jawbones of existing rhinoceros, hippopotamus, and antelopes; indeed, the site is littered with the horn-cores of the last.

Early this year, Dr. H. B. S. Cooke was invited by the University of Cape Town to give a general report on the site, and with regard to its fossil content his evaluation was as follows: "The fossil material collected is better preserved and more complete than at any other Stone Age site in South Africa. The only comparable deposits elsewhere in Africa are at Olduvai in Tanganyika and at Omo in Abyssinia".

The Skull

In January of this year, Mr. Keith Jolly collected a number of pieces of human cranial bones, which were found lying contiguously on the sandy surface. On a subsequent visit, the sandy area where the skull was found was systematically sifted, but nothing was found. Later expeditions, however, made valuable additions to the original material, the wind having in the interval exposed these fragments lying some yards away from the original find.



Vertical aspect of the Saldanha skull and of a cast of the Rhodesian skull

The skull, as it now stands, has been built up from twenty-five fragments of its frontal, parietal and occipital bones, and its original owner has been given the local name of 'Saldanha man'. The most striking feature of this skull is its massive brow-ridges and sloping forehead, which compel one at once to institute a comparison with Rhodesian man. In these respects and in the relative lowness of his cranial vault, there is no doubt that there are close affinities between the Saldanha and Rhodesian skulls. There are, however, significant differences, in that the Saldanha skull lacks the post-parietal depression or dent which the Rhodesian shares with the true Neanderthal skulls. In this respect the Saldanha skull resembles Solo man from Java, the recognized Neanderthaloid successor of *Pithecanthropus* (the ape-man of Java). Indications from the attachments of the muscles of the nape of Saldanha man's neck point to his having had the crouching posture of Neanderthal man, whereas the Rhodesian skull shows that he held his head erect like sapient man.

The walls of the Saldanha skull are extremely thick, and I estimate its capacity as in the region of 1,200–1,250 c.c.; that is to say, he had less brain matter than either the Rhodesian or the general run of Neanderthal skulls. Much more significant, however, in my opinion, is the sub-Neanderthal and most definitely sub-Rhodesian disposition of the Saldanha cerebellum in relationship to the occipital lobes of his cerebrum. On the evidence available I have come to the conclusion, therefore, that Saldanha man is anatomically a more primitive variety of the Rhodesian race.

With regard to age, I think I am justified in excluding the Still Bay implements (Middle Stone Age) from being regarded as more than a criterion of terminal dating value. This industry is found in many of the caves in South Africa, and, so far, there has been no suggestion of anything but a sapient type of man as its exponent.

The remaining possible association is with the late Stellenbosch (Chelles-Acheul) and Fauresmith (proto-Mousterian) facets of our Earlier Stone Age (lower palæolithic). That is to say, it would seem that it was a palæoanthropic type of man, such as the Saldanha skull undoubtedly reveals, who practised the last stages of the hand-axe culture in South Africa. This implies an association of the skull with the oldest of the fossil fauna, a view which is greatly strengthened by its equivalent heavy fluorine content, as shown by tests kindly undertaken for us by Dr. K. P. Oakley, of the British Museum (Natural History).

This article is written on behalf of the Hopefield Committee of the University of Cape Town, and with acknowledgments to those benefactors who made funds available for the investigation of the site.

OBITUARIES

Dr. Edwin P. Hubble

The death of Dr. E. P. Hubble from a heart attack, on September 28 at the age of sixty-three, has robbed the world of astronomy of its leading authority on nebulæ. Born on November 20, 1889, at Marshfield, Missouri, Hubble graduated at the University of Chicago in 1911 and proceeded to the Queen's College, Oxford, as a Rhodes Scholar. He obtained first-class honours in jurisprudence; but his plan to follow a legal career was abandoned when he received an invitation to carry out research at the Yerkes Observatory. His first published paper was on a variable nebula—now known as Hubble's variable nebula. In the First World War he commanded a battery in the U.S. National Army, but reached France only a month before the end of the war. He then spent the best part of a year in Oxford awaiting transport to the United States and demobilization. In the Second World War he worked in the supersonic wind-tunnel laboratory of the United States.

On his return home in 1919 after the First World War, Hubble was appointed to the staff of the Mount Wilson Observatory. He soon established his position as a leading worker in the field of the nebulæ. He showed that diffuse nebulæ owe their illumination to stimulation by radiation from hot stars. He then turned to the classification of the spiral nebulæ and showed conclusively that they are stellar systems lying outside our galaxy. He established a scale of distances from a study of the brightest stars and Cepheid variables in the nebulæ. Working with Humason and the 100-in. telescope, he established the velocity–distance law from the red shifts of lines in the spectra; this increased the reliable distances to which astronomers could plumb the depths of space up to 250 million light-years. He studied the law of the red shifts in all its bearings, aiming always at cutting down the number of conflicting interpretations, and he kept always an open mind on the kinetic or other explanations of the red shifts.

One of the main items on the programme of the 200-in. telescope on Mount Palomar was to secure evidence from the outermost regions of space—up to 900 million light-years—to determine whether expansion was the right answer to the problem and, if so, to find the exact law governing the expansion. It was tragic that Hubble did not live to see this investigation carried through to the end. His last account of the stage reached up to the present was given in the George Darwin Lecture at the Royal Astronomical Society last May.

Hubble was in great demand as a lecturer. In Great Britain he gave the Halley Lecture at Oxford and a course under the Rhodes Trust which was published as "The Observational Approach to Cosmology". His other well-known book is "The Realm of the Nebulæ". He received many awards and honours from learned societies and academies. In Great Britain he was made an Associate of the Royal Astronomical Society (1928) and Hon. D.Sc., Oxford (1939). He received the Gold Medal of the Royal Astronomical Society (1940) and was elected an Honorary Fellow of the Queen's College, Oxford (1949).

F. J. M. Stratton

Prof. H. Bompas Smith

Henry Bompas Smith, professor of education in the University of Manchester from 1912 until he reached the retiring age in 1932, died recently at the age of eighty-six. He was at school at Jena before winning a scholarship at Wadham College, Oxford. After a short time as an assistant master at Shrewsbury School, he was headmaster successively of Queen Mary's School, Walsall, and the newly founded King Edward VII School, Lytham. His work at Lytham made him known at the University of Manchester, and caused the University to offer him a chair which carried with it the directorship of the University Department of Education. There was already an endowed chair of education at Manchester, the Sarah Fielden professorship, which had been occupied for some ten years by the brilliant but somewhat erratic J. J. Findlay, who was more of an idealist than an administrator. Bompas Smith was brought in and given the headship of the Department, primarily to ensure that the wheels should run smoothly, and that the necessary contacts with schools, local authorities and the Board of Education should be handled by an experienced headmaster. It did not work out quite like this. He used to tell that before he had held his chair for six months, his views were brushed aside at a teachers' conference as those of "a mere theorist"; and in any event, in his later years at Manchester, he was more of a thinker than an organizer, though he was notably successful as chairman of the Northern Universities Joint Matriculation Board.

His main intellectual interest lay in philosophy. His best-known book, under the unrevealing title of "The Nation's Schools", is an interesting, and by no means unsuccessful, attempt to inculcate a somewhat conservative philosophy of education without using technical terms. He kept in touch with current developments in psychology, serving to the end of his life on the advisory board of the *British Journal of Educational Psychology*. But he made no original contributions in this field, and was never disposed to believe that a knowledge of psychological theory or technique could replace common sense as part of a teacher's equipment.

Bompas Smith was a kindly man, and genuinely interested in people, but not very quick in getting to know others or making himself known; and this handicapped his relations with the large annual batch of graduates at Manchester whom he taught for their postgraduate course in education. Most of them did not really get to know him, nor he them. Those few who did, obtained real benefit from his wise and balanced outlook upon life in general and education in particular. He disliked controversy, and the Manchester Senate of those days abounded in doughty controversialists. Perhaps he was too reluctant to speak up for his Department, and perhaps, for this reason, the University tended to under-estimate him. But he secured and retained the loyalty and affection of the staff of his own Department.

JAMES DUFF

NEWS and VIEWS

Jenner Medal of the Royal Society of Medicine: Mr. A. T. Glenny, F.R.S.

ON October 10 Mr. A. T. Glenny was presented with the Jenner Medal of the Royal Society of Medicine, which is awarded on the recommendation of the Section of Epidemiology, for distinguished work in the field of epidemic diseases. Mr. Glenny began his career in 1900 at the Wellcome Physiological Research Laboratories, became head of the Immunological Department before the First World War and retired under the age limit in 1947. He continued to carry on research at the Laboratories after his retirement and is still active after a period of yet unbroken association with the Laboratories of more than fifty-three years. His major concern has been the study of animal responses to soluble bacterial toxins and toxoids, made largely in the course of the routine production of antitoxin in horses. He developed the Römer guinea-pig skin test into a method of assay for diphtheria antitoxin, which is as accurate as many chemical titrations of simple substances. He has taken advantage of the variation of the response of horses to different toxins, to analyse by antitoxin titrations the great complexity of the antigenic constitution of filtrates of cultures of pathogenic anaerobes. Mr. Glenny's most important work is the study of the two types of response to the injection of antigens, the 'primary' and 'secondary' response, which has been fundamental to the development of methods of large-scale prophylaxis against diphtheria and tetanus. This study led to the development of alum-precipitated toxoid, now the standard prophylactic against diphtheria, which has been used with such dramatic results in the past decade in the control of diphtheria in Great Britain.

The Carnegie United Kingdom Trust: Mr. D. N. Lowe, O.B.E.

MR. DAVID N. LOWE, who has been secretary of the British Association for the Advancement of Science since 1946, has been appointed secretary of the Carnegie United Kingdom Trust in succession to Mr. J. Wilkie, who is due to retire on March 31, 1954. Mr. Lowe, who was born in 1909, was educated at Arbroath High School and at the University of St. Andrews, which he entered as a Kitchener Scholar. He was awarded a blue for hockey, founded a mountaineering club, and held many student offices, including the presidency of the Union and the Students' Representative Council. He graduated M.A. (English and history) and B.Sc. (with first-class honours in botany). After a short period of research on the marine algæ of the coasts of Fife, he became the assistant secretary of the British Association in 1935. At the outbreak of war he accepted an invitation to enter the Civil Service, where he served in the Cabinet Secretariat as secretary of various ministerial committees concerned with priority and allocation of materials. Shortly before returning to the British Association as secretary he was awarded an O.B.E. in the New Year Honours List of 1946. Mr. Lowe has been prominent in local affairs at Dorking, where he has held office in the Congregational Church, and has participated annually in the Leith Hill Musical Festival. It is as secretary of the British Association that Mr. Lowe has become widely known, however, and his services in the critical post-war period, when the fate of the British Association was in the balance, were invaluable. He has filled his present post with distinction, and the fund of goodwill which has remained after recent meetings has been largely due to his exceptional tact and organizing ability.

William McIlrath Fellowship for Research and Teaching in Animal Husbandry

THE Australian Commonwealth Scientific and Industrial Research Organization has decided to apply a gift of £A50,000 from Mr. William McIlrath, owner of the Windsor Hereford Cattle Stud, Delungra, N.S.W., to found the William McIlrath Fellowship for scientific research and teaching in the broad field of animal husbandry. The first to be appointed to this Fellowship is Dr. M. C. Franklin, principal research officer at the Organization's McMaster Animal Health Laboratory, Sydney, who has been engaged on research on animal husbandry for many years, and whose work on animal nutrition is well known. Dr. Franklin will be concerned mainly with work on beef cattle dietetics, and his research will be undertaken in collaboration with the Faculty of Veterinary Science of the University of Sydney and with the Division of Animal Health and Production of the Commonwealth Scientific and Industrial Research Organization. His work will add to the Organization's increasing programme of research on problems affecting the Australian cattle industry while at the same time strengthening university teaching and research. It is clear that there is a great potential for increased production in Australia through the application of scientific knowledge in feeding, breeding methods and other problems of animal husbandry.

David Livingstone Statue

On October 23, a statue of David Livingstone, missionary and explorer, was unveiled at the House of the Royal Geographical Society by Mr. Oliver Lyttelton, Secretary of State for the Colonies. The bronze statue, which occupies a niche in the north wall overlooking Kensington Gore, is the work of Mr. T. B. Huxley-Jones, of Chelmsford. The cost has been largely met by a generous donation from Lord Catto, and in part from the capital of a fund raised in 1903 to set up and maintain a memorial to Livingstone near Lake Bangweulu, which has now passed into the care of the Northern Rhodesia Commission for the Preservation of Natural and Historical Monuments. At the meeting preceding the unveiling, Mr. J. M. Wordie, president of the Royal Geographical Society, described the support which the Society had given to Livingstone and the warm friendship between the explorer and Sir Roderick Murchison. Mr. Lyttelton spoke of the obligation on those now helping the African people to follow the example of patience, tolerance, humanity and dedication set by David Livingstone. Dr. Hubert Wilson, a grandson, representing the Scottish National Memorial to Livingstone Trust, Blantyre, and the Rev. Maxwell O. Janes, of the London Missionary Society, also spoke. One hundred years ago Livingstone was engaged in the first of the three great journeys on which his fame as an explorer rests. On these journeys he pursued unremittingly the objects of his life's work in Africa—the spreading of the Gospel, the acquisition of knowledge of the interior, the fight against the slave trade, and the improvement of the moral and material conditions of the people—and thus initiated a momentous century in the history of Central Africa.

Education for Management

The rapidly growing interest in education for management in Great Britain is often accompanied by references to the lack of facilities compared with those of the United States. The comparison is often unavailing because precise information about the exact position in Great Britain has not been available. To fill the gap, the British Institute of Management has now produced a survey of administrative studies in Britain. This is in two volumes. The first, which has recently been published, covers subjects in the management field taught at universities and national, technical and commercial colleges of further education, and in the courses organized by professional and educational bodies. The second volume will cover short courses at residential institutions and university extra-mural establishments, and training courses carried out by professional and educational bodies and by trade unions, trade associations and individual firms. The survey lists nearly 220 major educational establishments which are known to teach subjects in the management field, including twenty-six universities and fifteen of the larger technical colleges. These two volumes should provide essential raw material for the evaluation of management courses. They should also serve as invaluable guides to all those concerned with management education and training, to lecturers and heads of departments, to training officers in industry and commerce, and to students of management subjects.

Scientific Translations Center of the Library of the United States Congress

The National Science Foundation, with the partial support of the United States Atomic Energy Commission, has set up an organization in the Science Division of the Library of Congress for holding and photoduplicating foreign scientific translations. This body, which will be known as the Scientific Translations Center, will collect its material from many sources, including government agencies, scientific societies, industrial laboratories and universities. Initially, the major emphasis will be on translations from Russian scientific journals, although it is hoped eventually to add material from other languages. Monthly lists of translations newly received will be issued by the Library of Congress; such lists will include notices of translations that are available by direct purchase from commercial and other translating services, but the Center will not supply photocopies of this material. The price list for copies of translations will be as follows: photostats or enlarged microprints, 1.25 dollars for 1–10 pages and 1.75 dollars for 11–15 pages; microfilms, 1 dollar for 1–50 pages. All inquiries relating to the new service should be addressed to the Scientific Translations Center, Science Division, Library of Congress, Washington 25, D.C.

Infra-red Spectra

The increasing use of infra-red spectra, and the expensive nature of the reproduction of these spectra on an adequate scale in journals publishing original research, has been placing such a burden on certain publishing societies that the Royal Society, the Chemical Society, the Physical Society, the Faraday Society, the Institute of Petroleum, and the Society of Public Analysts and Other Analytical Chemists, as well as other interested bodies, set up a joint committee to investigate the matter. The report of the committee, which has now been accepted by the societies, recommends conditions which should be satisfied before infra-red spectra are reproduced in published papers and lays down the format to which such spectra should conform. The committee is investigating the possibility of setting up some organization which will undertake the publication of infra-red spectra, preferably in collaboration with one or other of the American organizations that exist with the same object. As an interim measure, until a full library scheme is in operation, the Chemical Society accepts for deposit copies of infra-red spectra referred to or published in new papers in its own journals, and offers its facilities to other societies publishing original research. It should be emphasized that deposition of spectra is voluntary on the part of the author, with the object of the spectra being generally available in a form larger than can be printed; it is not a condition of acceptance of papers for publication. All spectra deposited with the Society must be drawn in indian ink, with all other lettering in pencil, on forms obtainable from the General Secretary, Chemical Society, Burlington House, Piccadilly, London. W.1, price 6s. per pad of fifty sheets. Photocopies of spectra thus deposited are made available to the public on request to the general secretary of the Society; applications must quote the C.S. number of the spectra desired and must be accompanied by a remittance of 3s. per copy per spectrum (post-paid), special rates being available for a large number ordered at one time. Fifty spectra which are already available will be listed in *Proceedings of the Chemical Society* of December 1953; further lists will be published quarterly in the *Proceedings*, and annual lists will be published in the index volumes of the *Journal of the Chemical Society*.

Rhizomorph Formation in *Armillaria mellea*

THE importance of the rhizomorph in the evolution of fungi causing root disease has led to further experimental study of the inception and development of the rhizomorphs of a strain of the honey agaric (*Armellaria mellea*) under controlled cultural conditions (S. D. Garrett, *Ann. Bot.*, N.S., 17, 65, 62; 1953). When a disk of mycelium taken from the margin of a colony is laid on a fresh agar substrate, mycelial growth begins within twenty-four hours and rhizomorph initials can be seen after seven days. The young rhizomorphs have a maximum growth-rate which is about five times that of the normal hyphæ, the characteristic lobed appearance of colonies being largely due to this fact. An interaction was found between carbohydrate and nitrogen in their effects upon both the initial formation of rhizomorphs and their subsequent growth: as the carbohydrate concentration of the medium was increased, so the optimum concentration of nitrogen for the inception and growth of rhizomorphs increased. On a medium of suitable nutrient composition, no independent rhizomorph initials were observed apart from those originally formed around the inoculum disk. On the basis of experimental evidence it is considered that a certain threshold nutrient status is essential for rhizomorph initiation. Once a rhizomorph has started to grow on an agar plate, the depletion of nutrients in its vicinity prevents the formation of new initials.

Microscopes and Accessory Equipment

THE new microscope catalogue of R. and J. Beck, Ltd. (69 Mortimer Street, London, W.1), covers a wide range of microscopes and accessories. It gives details of several new types including the reflecting microscope and the universal microscope, and apparatus is described for vertical phase-contrast illumination and fluorescence microscopy. A welcome addition for many workers will be the 35-mm. photomicrographic camera. A notable feature of the Beck equipment is that it is largely designed as interchangeable units. The catalogue has eighty pages, is pleasantly and clearly produced and should be of interest to all microscopists.

Luminescence: Conference in Cambridge

THE Electronics Group of the Institute of Physics is organizing a conference on luminescence, with particular reference to solid inorganic phosphors, which will be held in Cambridge during April 7–10, 1954. The first half-day of the meeting will include a lecture on the present scope of the subject and its developments since the last conference of this kind (Faraday Society, Oxford, 1938). The next day, April 8, will be devoted to papers on phosphor applications and future prospects, especially in the fields of cathode-ray tubes, lighting, electroluminescence and scintillation counting. Papers on the physical chemistry and atomic structure of phosphors, both sulphide and other types, and especially on the nature of the luminescence centre, will be read on April 9. On the last day more theoretical ideas on luminescence will be considered, such as the absorption, emission, transport and storage of energy, and the theory of activator systems. During the conference there will be an evening lecture with demonstrations on unsolved problems in luminescence. Further information can be obtained from Dr. S. T. Henderson, Institute of Physics, 47 Belgrave Square, London, S.W.1.

British Institute of Management

THE British Institute of Management has recently issued details of its pioneer executive development programme which provides for a series of four-weekly courses to be held at Management House, Hill Street, London, W.1, at intervals over the coming year. The first course opens on November 1. The programme is specially designed to meet the needs of the established executive in the 30–40 age group whose experience to date has been in a particular specialization. The contents of the courses and methods employed are based on recognition of the fact that successful management depends substantially upon the possession of certain thought habits and attitudes of which analytical ability and a social sense are perhaps the most fundamental. Thus corporate life, syndicate work, exercises and reports, speech-training and committee work are vital ingredients of the programme—no wit less important than the informatory lectures which cover the broad field of management and the best current methods. Of particular interest to those concerned in the running of courses is the modification of the case-study procedure to a form appropriate to the maturity and experience of members of the course. In the American schools of business where the case-study method is a significant feature, the preoccupation is with students with little or no executive experience, and the task is therefore different. This facet of the programme is a recognition of a basic difference between contemporary provision in the American schools of business —such as Harvard—where the majority of students have little or no previous experience, and the situation in Great Britain, where the climate of opinion demands that a man should have experience of industry before he undertakes a course of this kind which is designed to develop his managerial ability.

Another interesting feature is the concept of providing a course to aid the individual and personal development of the student. Thus the entire programme permits only twenty-four students working for the greater part of the time in smaller groups. In fact, the extent of personal development can be in direct proportion to the extent of individual participation. The lecturers and tutors are in the main drawn from industry and are persons of substantial experience in the field they cover. The Institute emphasizes the pioneer nature of the series and hopes that the results of its experiences will be made available for the development of management training on a much wider scale.

The Night Sky in November

New moon occurs on Nov. 6d. 17h. 58m., U.T., and full moon on Nov. 20d. 23h. 12m. The following conjunctions with the moon take place: Nov. 3d. 09h., Mars 6° N.; Nov. 5d. 03h., Venus 7° N.; Nov. 8d. 01h., Mercury 2° N.; Nov. 22d. 19h., Jupiter 3° S. In addition to these conjunctions with the moon, Venus is in conjunction with Saturn on Nov. 14d. 04h., Venus being 0·9° S., and Mercury is in conjunction with Venus on Nov. 23d. 17h., Mercury being 1·2° N. Mercury is in inferior conjunction on November 14 and is not well placed for observation until about the third week in the month; on November 30 it rises nearly two hours before the sun and can be seen in the eastern sky, but owing to its fairly large southerly declination it will not be far above the horizon about the time of sunrise. Venus, a morning star, rises at 4h. 30m., 5h. 30m. and 6h. 20m. on November 1, 15 and 30, respectively. Its stellar magnitude is – 3·4, and the visible portion of the illuminated disk varies from 0·93 to 0·97. Mars, a morning star, rises at about 3h. during November; in the early part of the month it is nearly midway between ρ and η Virginis, and its easterly movement takes it near θ Virginis towards the end of the month. Its stellar magnitude is about 1·9 during most of November, but towards the end of the month it becomes a little brighter and continues to grow brighter for the remainder of the year. Jupiter rises at 18h. 55m., 17h. 55m. and 16h. 50m. on November 1, 15 and 30, respectively, and is conspicuous during the night (stellar magnitude – 2·5) in the constellation Taurus. Saturn, a morning star, is too close to the sun at the beginning of the month to be seen, but at the middle and end of the month it rises at 5h. 15m. and 4h. 30m., respectively, and can be seen in the constellation Virgo not far from the fourth-magnitude star κ Virginis. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Nov. 16d. 17h. 25·3m., λ Pisc. (*D*); Nov. 21d. 01h. 12·8m., η Taur. (*D*); Nov. 21d. 01h. 38·6m., η Taur. (*R*); Nov. 24d. 0h. 04·4m., 87 B. Gemi. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Leonid meteors are due about November 16–17, but moonlight will partly interfere with the observations; this shower is very weak and supplies comparatively few meteors now. The Andromedid meteors are due about November 28, and this shower also is very weak compared with what it was in previous years. A transit of Mercury over the sun's disk on November 14 is partly visible at Greenwich: for the ingress, the exterior contact occurs at 15h. 35m. 42s., U.T., and interior contact at 15h. 39m. 12s.; the egress is not visible in the British Isles.

Announcements

Dr. P. H. Gregory, mycologist to the Plant Pathology Department at Rothamsted Experimental Station, has been appointed to the University of London chair of botany tenable at the Imperial College of Science and Technology, in succession to Prof. W. Brown, who is retiring.

Prof. W. T. Astbury, professor of biomolecular structure in the University of Leeds, has been awarded a medal by the American Society of European Chemists for his outstanding contribution to international scientific relations.

Sir Noel Ashbridge, director of technical services of the British Broadcasting Corporation, has been made an honorary member of the British Institution of Radio Engineers, in recognition of his notable contributions to the whole field of radio engineering.

Dr. W. A. Jenkins, director of studies in the University College of North Staffordshire, has been appointed vice-chancellor of the University of Dacca.

Mr. H. C. Pritchard, recently chief superintendent of the Long Range Weapons Establishment in Australia, and formerly head of the Instrument and Air Photography Department of the Royal Aircraft Establishment, has been appointed deputy general manager in charge of science in the firm of Elliott Brothers (London), Ltd.

The new laboratories of the British Iron and Steel Research Association at Hoyle Street, Sheffield, are to be opened by the Duke of Edinburgh on November 19. The laboratories include those of the Cutlery Research Council. Applications for invitations to inspect the laboratories on November 20 should be made in writing to Max Davies, B.I.S.R.A., 11 Park Lane, London, W.1, by November 10.

The following lectures are announced in the programme for November and December issued by the Royal Society: Leeuwenhoek Lecture, by Dr. K. M. Smith, on "Some Aspects of the Behaviour of Certain Viruses in their Hosts and of their Development in the Cell" (November 5); Ferrier Lecture, by Sir Francis Walshe, on "The Contribution of Clinical Observation to Cerebral Physiology" (December 10). Mr. A. H. Wilson will deliver a lecture on the Research Department of Courtaulds, Ltd., on November 12. The Parsons Memorial Lecture for 1953 is being arranged by the Institution of Electrical Engineers, and will be given on January 7 by Mr. H. Leyburn, on "Continuity of Electricity Supply".

The H. K. Sen Memorial Lecture of the Institution of Chemists (India) will be given this year by Dr. S. Husain Zaheer, director of the Hyderabad Central Laboratories for Scientific and Industrial Research and professor and head of the Department of Chemical Technology, Osmania University.

The National Institute of Agricultural Botany will hold a crop conference in Cambridge during December 15–16 on the lines of the one held last year. The subjects to be discussed will include barley varieties, quality in wheat and sugar beet. Further particulars can be obtained on sending a stamped (1½*d*.) addressed envelope to the Secretary, N.I.A.B., Huntingdon Road, Cambridge.

To mark the first anniversary of the death of the late President Chaim Weizmann, a number of scientific events will take place in Israel at the Weizmann Institute of Science during November 2–6. The new building of the Biological Institute will be officially opened and the corner-stone of the Physics Institute laid. Symposia will be held on various subjects connected with biology, biochemistry, polymers and physics. Further information can be obtained from the Academic Secretary, Department of Mathematics, Weizmann Institute of Science, Rehovoth, Israel.

IONIZATION PHENOMENA IN GASES

THE Physical Society, the Institute of Physics and the Electrical Research Association were the sponsors of the first international conference on "Ionization Phenomena in Gases", held at the Clarendon Laboratory, Oxford, during July 18–23. The 250 visitors included many distinguished foreign guests from ten countries. Social activities were held over the week-end, beginning with a reception at Christ Church at which Lord Cherwell and Sir John Townsend were present. There were conducted tours of Oxford colleges and a garden party given by the British Council for overseas visitors. Later in the week ladies visited Blenheim Palace, a blanket mill at Witney and the theatre at Stratford-upon-Avon. Receptions were also given by the British Electricity Authority, and by the Mayor of Oxford.

The conference was opened by Dr. A. von Engel, who surveyed the work in Great Britain. The delegates were also welcomed by Mr. T. C. Keeley, director of the Clarendon Laboratory. Chairmen at the sessions were, respectively: Dr. S. Whitehead, Dr. C. Sykes, Mr. R. Davis, Mr. E. W. B. Gill, Dr. E. J. Bowen, Sir John Cockcroft, Dr. T. E. Allibone and Prof. R. Whiddington.

The main subjects discussed were spark, arc, glow and high-frequency discharges, Geiger counters and several fundamental processes.

There were two schools of thought on the formation of sparks: one ascribing their development to photoelectric action in the gas aided by multiplication in the electric field; the other to secondary processes at the cathode again aided by Townsend multiplication. In support of the first, J. D. Craggs (Liverpool) gave measurements of the rate of the radial expansion of spark channels at high pressure. He discussed how closely thermal equilibrium is attained in the spark channel and noted the observed differences in the 'excitation temperatures' of the various emission lines. J. M. Meek and R. F. Saxe (Liverpool) showed from their measurements on sparks up to 100 cm. long how streamers grow in time and space just before a final breakdown.

The other idea is that Townsend's theory adequately describes all the conditions leading to breakdown, and applies equally to low and high pressures. F. Llewellyn Jones (Swansea) reviewed this theory and showed that, with extremely stable cathode conditions and electric fields, ionization currents increase with distance as predicted by Townsend. This is true even when pressure is greater than 760 mm. mercury and up to voltages approaching the breakdown value. In the discussion, he suggested that in impulse fields, luminosity, which depends on high ion density, may appear at the anode, later moving quickly towards the cathode. C. Grey Morgan (Swansea) stressed the importance of field emission caused by surface layers on metal cathodes.

L. H. Fisher (New York) described the marked effect of excess voltage on the formative time lag. When the voltage is just above threshold, the lag is about 10^{-4} sec. in air, nitrogen, argon and oxygen. This again supports Townsend's theory and points to photoelectric emission at the cathode, except in argon, where there is a long delay even at high excess voltages, probably due to imprisonment of resonance radiation. C. E. R. Bruce (Electrical Research Association) pointed out that breakdown fields in air for extremely long gaps (for example, between clouds and earth) are about 100 V./cm., which shows that the starting process must be different from that with uniform fields and metal electrodes. Corona currents which flow radially outwards from streamers were mentioned, and certain solar eruptions were likened to long sparks.

In the session on arc discharges, R. Mannkopff (Göttingen) discussed radiation equilibria. By examining spectral intensities he showed that after an arc is switched off, thermal excitation and ionization persist, and must have predominated previously. Auto-ionization appears to be a probable process. W. Lochte-Holtgreven (Kiel) described high-power arcs in water vapour giving temperatures of about 50,000° K. The electron concentration is determined by the equation of Inglis and Teller, after observing the number of Balmer lines of hydrogen visible. The continuous background is partly caused by negative atomic hydrogen ions. H. Maecker (Erlangen) showed how, by varying the pressure in such arcs between 100 and 1,000 atmospheres, one can discriminate between, and measure, the cross-sections for electrons colliding with neutral atoms and positive ions. M. Hoyaux (Charleroi) described the use of Ledrus's 'plasmograph', recording Langmuir's probe characteristics in mercury rectifier discharges with a time resolution of less than 20 microsec.

P. F. Little (Oxford) opened the session on glow discharges by describing how the electric field distribution in a hollow cathode discharge in nitrogen can be measured. The deflexions of an electron beam show a linear fall of field with distance from the cathode down to very small values at the boundary of the glow. The large current density observed is explained by a large ion concentration and ion-drift velocity. He concluded that many electrons are emitted from the cathode by light from the intense glow. W. Fucks (Aachen) has used corona discharges to measure aerodynamic effects, notably the appearance of vortices, and the associated flow of gas. W. L. Harries (Oxford) discussed the abnormally low starting fields in high-frequency electrodeless discharges in neon; he attributes them to the production of a large concentration of excited atoms which are later ionized by low-energy electrons released by light from the glass walls. G. Valle (Bologna) has applied relaxation oscillations of increasing frequency to a discharge in argon or neon. The restriking potentials decrease when the residual ionization from the afterglow becomes important. W. A. Prowse (Durham) showed that in microwave discharges ionization is due to electron collisions and loss to diffusion. With short pulses, however, a critical electron density has to be reached within the pulse-time to obtain breakdown. In polyatomic gases, a formative lag of less than 10^{-8} sec. is observed. It is suggested that the oscillating electrons produce excited molecules which are readily ionized. This idea is being tested by applying an auxiliary D.C. electric field at right angles which drives the electrons into unexcited gas. Oscillograms of the current in pulsed high-frequency electrodeless discharges were presented by G. Francis (Oxford), who discussed the mechanism of growth of current. He showed that in hydrogen two secondary processes, one fast and one slow, are necessary. S. C. Brown (Massachusetts Institute of Technology), injecting electrons into a low-pressure mercury plasma, observed plasma oscillations only when ion sheaths were present around the electrodes. Their frequency depended on the density of the electrons which oscillate in certain standing-wave forms. From the variation of the frequency with the thickness of the sheath, it follows that a 'transit-time process' causes these oscillations. D. C. Dalton (London) reported experiments which indicate the effect of space charges on the breakdown of high-frequency discharges in air.

In the following session, G. L. Weissler (Los Angeles) described his vacuum spectrographic measurements in rare and molecular gases, which yield the absorption coefficients as a function of the wave-length and thus the photo-ionization cross-sections. Preliminary results have also been quoted of photoelectric yields on various metal surfaces, again for wave-lengths between 100 and 1000 A. In the discussion, W. B. Nottingham (Massachusetts Institute of Technology) mentioned some results obtained with pure silica. P. J. Jutsum (Reading) compared his experimental results of photo-ionization cross-sections in sodium, magnesium, calcium and thorium vapours with the calculated values and described a method of discriminating between molecular and atomic absorption. In a written communication, A. and E. Vassy (Paris) described the character of spectra of sparks in air of 15–150 cm. length; a study of the spectral lines as a function of the time has also been made. G. Valle (Bologna), in a paper read by R. W. Lunt, described his theory of breakdown in a transverse magnetic field. This field is supposed to have the same effect as an increase in density of gas. Assuming only inelastic collisions with electrons of constant mean free path, he obtains results which agree roughly with experiments. J. M. Somerville (Sydney), extending this theory, included the distribution of free paths and the partial capture of electrons driven back to the cathode by the field. He also described the effect of transverse fields on the length of the dark space in glow discharges between concentric cylinders.

In the session on counters, R. Loosemore (Harwell), in a paper read by W. Abson, discussed certain features of the bromine-quenched counter. At a critical voltage a second pulse appears, due to another discharge between ion sheath and cathode. The probable origin of spurious oscillations was also discussed. P. J. Campion (Oxford) showed cloud-chamber photographs of the propagation of a Geiger discharge along a counter wire in an air–alcohol mixture; the charge distribution within the ion sheath was measured. H. den Hartog (Amsterdam) spoke about the electron component in the Geiger discharge, which he thinks may be explained by the large radius of the space charge at high excess voltages. A group of Italian workers, L. Colli, U. Facchini, G. Bertolini and others (Milan), presented papers on the mechanism of argon-filled counters. α-Particles were used to trigger light and electron current pulses which were observed simultaneously. The light pulse lasts longer, due to the long life of metastable argon atoms and excited molecules. Current oscillograms from counters with nickel or brass cathodes show that their photoelectric yield must be of the order of 10^{-3}. Ionization currents in argon with small amounts of polyatomic gases were found to differ from those theoretically expected. This is sometimes due to interaction between the components of the mixture, sometimes to ionization by δ-rays (slow electrons).

High-vacuum studies were introduced by R. L. Fortescue (London), who talked about breakdown in highly evacuated gaps. Bursts of current precede the development of an arc and depend on the condition of both electrodes. J. W. Leech (London) presented calculations on these pulses, assuming that the electrons are confined to narrow channels, and estimated the gas pressure necessary to make them diverge. D. Alpert (Pittsburgh) reviewed the existing ultra high-vacuum technology and described new methods of obtaining a pressure so low as 10^{-10} mm. mercury without getters or refrigerants. S. Wagener (General Post Office, London) showed that the high gettering rates of barium can only be understood by assuming that the reacting gas particles are atoms, not molecules. Selective getters were also treated. J. H. Mason (Electrical Research Association) showed oscillograms and Lichtenberg figures of pulse-discharges in cavities in dielectrics when subjected to low-frequency fields and offered tentative explanations.

In the last session, R. Geballe (Seattle) described simultaneous measurements of ionization and attachment coefficients and discussed quantitatively the effect on the ionization current as a function of the electrode separation. N. L. Oleson (Monterey) presented preliminary work using Langmuir probes and photomultipliers for measuring simultaneously charge density and light from striations in an argon positive column. Kantrowitz (Cornell) reported measurements on ionization and light produced in argon and in argon–oxygen mixtures by shock waves.

GROUP DISCUSSION

In view of the increasing use which is being made of discussion groups as an educational medium, the editors of the *Health Education Journal* are to be commended for devoting the whole of a recent issue to the subject of group discussion (11, No. 3; July 1953). The theory of group discussion is introduced by Dr. M. L. Johnson, who suggests that the disadvantage of the lecture as a teaching method is that there is no 'feed-back' to the teacher; he cannot know what is selected or how what is absorbed is distorted. He can only try to present the material in a manner which, from his judgment of the listeners' backgrounds, he considers interesting and unambiguous, so that they will absorb as much, and in as undistorted a form, as possible. This disadvantage does not apply to the discussion method; but, to be successful, discussion must be carried out in a "permissive atmosphere". This is essential because people must not be allowed to feel afraid of making fools of themselves by exposing the irrationality of their thinking and feeling. They must feel free to talk in a spontaneous, even incoherent and random manner, so that assumptions can be brought to light and their usefulness examined.

The means of introducing discussion is examined by Dr. Emrys Davies, who indicates that, in most cases, discussion is educational in character because almost invariably it aims at modifying attitudes and changing behaviour. To be fully effective the leader of the discussion group should devote considerable time to preparation before meeting his group. Besides getting to know the background of his group, the theme chosen for discussion should have meaning and purpose in their lives.

The technique of running a successful discussion group is elaborated by Mrs. Margery Fassam, who considers that group discussions for training or teaching were introduced on the assumptions that we all have something to learn from each other, and that active participation in a teaching–learning session achieves better results through this co-operation than a straight lecture. By a process of questioning and discussing, the group can thoroughly explore a subject, and in this process the sum total of the knowledge and experience of the group comes into play. Ideas are modified by coming into contact and sometimes conflict with other ideas. Mrs. Fassam also gives some useful practical hints on the ways of conducting discussion groups, while Dr. Paul Polani writes of his experience in using organized discussion for investigating social problems in the pædiatric curriculum at Guy's Hospital Medical School, London.

The place of the discussion group as a potent force in health education is well brought out by Dr. John Burton, the medical director of the Central Council for Health Education, who also describes the film strips which his organization has produced for use with discussion groups.

The greater use of discussion groups in industry is advocated by J. J. Gillespie, who believes that small free discussion groups meeting regularly in paid time with participation by all primary workers within a business may be a remedy for the lack of personal significance and self-expression experienced by these workers in modern business organizations. While serving this purpose, the discussion groups are a likely way of healing the breach between work life and leisure life, and of solving the problem of relationships in work. Such discussion groups are already in existence in some firms and have proved worth while.

The final article has been written by Magda Kelber, a refugee in Britain during the War and who has now returned to Germany to become the head of Haus Schwalbach, a leadership training centre. The methods in use at Haus Schwalbach have been based on principles developed by Mrs. Rachel DuBois in the United States. These sprang from the need for integrating many different elements of racial, national and religious background in local communities which have their own patterns and their own sets of values and prejudices. Such a collection of people was found in Germany after the War, and Magda Kelber describes how the principles were adapted to meet local needs and interests.

HETEROSIS IN SACCHAROMYCES

By Prof. CARL C. LINDEGREN, J. EDGAR BRAHAM and JUAN DE DIOS CALLE

Biological Research Laboratory, Southern Illinois University, Carbondale, Illinois

FOUR different genes have been described in *Saccharomyces* which control the hydrolysis of alpha-glucosides, each gene producing a specific and different enzyme[1,2] (Table 1).

Table 1

Gene	Enzyme	Substrate
MA	Maltase	Maltose and turanose
MG	Alpha-methyl glucosidase	Alpha-methyl glucoside
SU	Invertase	Sucrose and raffinose (1/3)
MZ	Alpha-gluco-melezitase	Maltose, turanose, sucrose, alpha-methyl glucoside, and melezitose
?	Gluco-sucrase	Sucrose (not raffinose)

A culture of genotype *MA mg su mz* can grow on maltose and produce the adaptive enzyme maltase, but is incapable of growing on or adapting itself to alpha-methyl glucoside, sucrose, raffinose or melezitose[3]. A culture of genotype *ma MG su mz* can grow on alpha-methyl glucoside, but is incapable of fermenting any of the other alpha glucosides. The fact that alpha-methyl glucoside acts as the inductor of the enzyme alpha-methyl glucosidase is curious, since alpha-methyl glucoside is not a natural substrate and the ability to hydrolyse alpha-methyl glucoside is of no survival value. Hestrin and Lindegren showed that the culture of genotype *MA MG su mz* produces (in addition to maltase) alpha-methyl glucosidase (and gluco-sucrase) during growth on maltose, but neither invertase nor alpha-gluco-melezitase. This phenomenon was called heterologous adaptation[4]. The present article deals with the interactions of the *MA* and *MG* genes in diploid hybrids. The hybrids were made with haploids recessive for the genes controlling the production of invertase and alpha-gluco-melezitase to avoid the complications which would ensue because of the production of alpha-gluco-melezitase and invertase.

Methods. The haploids used for making the hybrids were *MA MG* (4), *MA mg* (2), *ma MG* (1) and *ma mg* (2). The different types of hybrids are listed in Table 2.

Table 2

	MA MG (4)	*MA mg* (2)	*ma MG* (1)	*ma mg* (2)
MA MG	$\frac{MA\ MG}{MA\ MG}$ (4)	$\frac{MA\ MG}{MA\ mg}$ (1)	$\frac{MA\ MG}{ma\ MG}$	$\frac{MA\ MG}{ma\ mg}$ (2)
MA mg		$\frac{MA\ mg}{MA\ mg}$	$\frac{ma\ MG}{MA\ mg}$ (1)	$\frac{MA\ mg}{ma\ mg}$ (1)
ma MG			$\frac{ma\ MG}{ma\ MG}$	$\frac{ma\ MG}{ma\ mg}$

Five kinds of hybrids were tested. The data appear in Table 3. All the haploids or hybrids carrying both the *MA* and *MG* gene showed the phenomenon of heterologous adaptation, but other cultures lacked this characteristic.

The cultures were grown on complete media containing (*a*) maltose or (*b*) alpha-methyl glucoside as the only added sugar, and harvested and tested for their rates of fermentation of glucose, maltose, alpha-methyl glucoside, sucrose, raffinose and melezitose. All tests on raffinose and melezitose were negative, showing that the cultures carried *su* and *mz* instead of their dominant alleles. Nitrogen was determined directly by a Nessler test. All cultures (with three exceptions) fermented glucose at rates of 2,000–3,800 $Q^{N_2}_{CO_2}$ (N).

In calculating the *Q* values (which are based on carbon dioxide evolved), those for maltose and sucrose were divided by 2 to equate them with those for alpha-methyl glucoside. Because alpha-methyl glucosidase liberates only a single molecule of hexose whereas maltase and gluco-sucrase each liberate two molecules of hexose, and because the rate of evolution of carbon dioxide is used as the measure of enzyme,

Table 3

		Cells grown on maltose				Cells grown on α-methyl glucoside

$\frac{14{,}268}{15{,}214}$	$\frac{MA\ mg}{ma\ mg}$	2,067	309	0	0	—	—	—	—

this correction equates the amounts of the three enzymes. No adaptations produced maltase in excess of the capacity of the cell to consume the glucose produced.

Results. Only those haploids or hybrids carrying the *MG* gene were able to grow on the medium containing alpha-methyl glucoside. Cells grown on alpha-methyl glucoside varied in ability to ferment alpha-methyl glucoside with *Q* values of 500–2,800. Four of fourteen fermented alpha-methyl glucoside and glucose at practically the same rate, suggesting that the alpha-methyl glucosidase was in excess of the capacity of the cell to utilize all the glucose made available by hydrolysis of alpha-methyl glucoside. None of the cultures grown with alpha-methyl glucoside was able to ferment maltose.

Only cultures carrying the *MA* gene were able to grow on the medium containing maltose. The $Q_{CO_2}^{N_2}$ (N) on maltose of haploid cultures grown on maltose and carrying the *MA* gene varied between 200 and 600. Culture 14,262 was much weaker but exhibited a generally low metabolic activity, since its activity on glucose was less than half that ordinarily shown.

The amount of alpha-methyl glucosidase produced by cells grown on maltose as a result of heterologous adaptation was always less than the amount produced by homologous adaptation.

Heterosis. All hybrids carrying either *MG/MG* or *MG/mg* were more active in fermenting maltose than the haploids from which they were produced, in spite of the fact that in the hybrids heterozygous for *MA* the gene 'concentration' for *MA* is reduced by one-half. Hybrid 14,268 × 15,214 *MA mg/ma mg* (homozygous for *mg/mg* had a *Q* value for maltose of 309, while the haploid parent (*MA mg*) had a higher value, namely, 538. The value for the hybrid (*MA/ma*) is approximately equivalent, on a gene basis, since the *MA* 'concentration' of the hybrid is one-half that of the haploid. Since the diploid cell is twice as large as the haploid, the *MA* 'concentration' in the haploid cytoplasm is twice as great as in the diploid. These results show that no special quality is conferred by hybridization, and that the hybrid is not *ipso facto* superior to the parent.

The average *Q* value of the maltose-grown haploids on maltose was 395, whereas the average *Q* value of the maltose-grown hybrids on maltose was 719, excluding 14,268 × 15,214. Many of the hybrids were heterozygous for *MA/ma*, thus reducing the 'concentration' of the *MA* gene by one-half; but in spite of the reduction in concentration, the increase in fermentative ability was spectacular. For example, haploid 8,324 (*MA MG*), with a *Q* value of 465 on maltose, was mated to 15,214 and produced a hybrid (*MA MG/ma mg*) which achieved a *Q* value on maltose of 1,140, an increase of nearly threefold on a nitrogen basis, and nearly sixfold on a gene basis. Hybrid 15,198 × 15,214 was also superior to 15,198, rising from a level of 179 in the haploid to 649 in the hybrid. In the absence of the *MG* gene, culture 15,214 does not confer any special improvement on the hybrid; this was shown in the analysis of the hybrid 14,268 × 15,214 (*MA mg/ma mg*).

The average *Q* value of the haploids grown on maltose tested on alpha-methyl glucoside was 314, whereas the average value of the hybrids was 402, although several hybrids were heterozygous for *MG/mg* and, therefore, carried a reduced concentration of the *MG* gene.

The data also indicate that the ability to produce gluco-sucrase is enhanced in the hybrids. The hybrid which failed to show an increase in maltase production produced neither alpha-methyl glucosidase nor gluco-sucrase.

Conclusions. The data suggest that the increase in maltase in the hybrid is due to a group of modifying genes of which *MG* is the principal member. A member of this group, different from *MG*, is present in 15,214, and may be inferred to have some effect on the production of gluco-sucrase. Although the *MA* gene alone can control the production of maltase, it functions much more effectively in concert with other genes, one of which effects the production of alpha-methyl glucosidase, while another may produce gluco-sucrase. *MG* is distinguished by its ability to react adaptively to alpha-methyl glucoside to produce alpha-methyl glucosidase. Although this enzyme has no biological value in terms of its ability to hydrolyse alpha-methyl glucoside, it may be involved in the synthesis of maltase. In the absence of *MA*, *MG* is incapable of responding to maltose. Lindegren[5] has inferred that the gene *MZ* is a receptor on which substrate acts to produce an impulse which finally results in the production of alpha-gluco melezitase. Assuming that *MA* (which appears to be closely related[5]) acts similarly, the effect of *MG* on *MA* may be to enhance the impulse from the *MA* locus to the site of enzyme production. In the presence of *MG*, the impulse from *MA* induced by maltose may result in the elicitation of alpha-methyl glucosidase, some of which can be converted into maltase. Another locus may cause the *MA* impulse to elicit gluco-sucrase, which is possibly convertible into alpha-methyl glucosidase.

This work has been supported by research grants from Anheuser-Busch, Inc., and the National Cancer Institute of the National Institutes of Health, Public Health Service.

PHYSIOLOGICAL RACES OF WHEAT STEM RUST IN EGYPT*

By Dr. T. ABDEL-HAK

Plant Pathologist, Ministry of Agriculture, Egypt

WHEAT stem rust is considered the most important disease which attacks this crop and the greatest hazard in its production. In Egypt this rust attacks the Hindi varieties (*Triticum vulgare*) and durums (*Triticum durum*), while Baladi varieties (*Triticum pyramidale*) are nearly immune. The loss caused by this rust to the Hindi varieties is estimated at about 500,000 erdebs (1 erdeb = 150 kgm.), which is worth about 2 million Egyptian pounds.

In normal years the damage caused by stem rust on the Hindi varieties is about 10 per cent of the total crop. Most of the damage occurs in lower Egypt (the Delta of the Nile) because of the high humidity which prevails in that area. About one million feddans (1 feddan = 1·038 acres) are cultivated with wheat in this area. In Upper Egypt, where about half a million feddans of wheat are grown, the severity of rust attack is less important.

Physiological specialization of *Puccinia graminis tritici* Eriks. and Henn., the causal organism of wheat stem rust, was first reported by Stakman and Peimisel in 1917. The first investigations on the specialization of this rust in Egypt were carried out by the writer in 1949.

The main object of the present investigation has been to identify the physiological races of *Puccinia graminis tritici* Eriks. and Henn. in Egypt and to study their geographical distribution all over the country. It was found desirable to study also the reaction of a great number of wheat and barley varieties to the existing races.

Such study may contribute information about the physiological races existing in Egypt and probably in other parts of the Middle East which may help in using these races in the breeding programme for rust resistance. On the other hand, identifying the races may help in tracing the movement of the uredio-spores of stem rust from one country to another and consequently shed some light on the proper materials to be exchanged among these countries for breeding for rust resistance.

Experimental Results

Identification of physiological races. Rust specimens were collected every year during April and May from different varieties of wheat grown in various localities and provinces of Egypt and were stored in the refrigerator during summer-time until the temperature became suitable inside the greenhouses for working on the identification of physiological races. The differential varieties and the method of identification used in this investigation are those used by Stakman.

In 1949 about seventy-four rust collections were used for race identification and about 253 isolates originated from these collections. Nine races of *Puccinia graminis tritici* Eriks. and Henn. were isolated. These races are 9, 14, 17, 19, 21, 24, 42, 88 and 123. A new race which is similar to race 17 was isolated in 1949 from a rust specimen collected from an unknown variety of wheat grown at Menshat Sultan, Dakahlieh. The reaction of the differential varieties to this race is similar to those of race 17 except that Acme is resistant to this new race. It was given the symbol E_1 (Egypt No. 1). Race 17 was the most prevalent one in that year. It was found in 47·85 per cent of the total isolates. Race 21 came second, race 19 third, and race 14 fourth, while other races were less frequent.

The work of 1950 on forty-four rust collections, giving rise to 170 isolates, revealed the existence of eight races of *Puccinia graminis tritici* Eriks. and Henn., namely, 9, 14, 17, 19, 21, 24, 42 and 53. Again race 17 was the predominant race. It was found in 43·5 per cent of the total isolates. With regard to the other races there was fluctuation in their prevalence in comparison with the results of the previous year. Race 19 was the second, race 42 the third, while race 21, which was the second in 1949, became the fourth in 1950. The other races were also of minor importance in 1950.

In 1951 identification of physiological races was handicapped by unforeseen circumstances. On account of this, only nine rust collections were good to work with. About seventeen isolates were made, giving rise to races 17, 19, 42 and 59 of *Puccinia graminis tritici* Eriks. and Henn. Despite the small number of rust isolates in 1951, race 17 was the most prevalent race. Race 59 was isolated for the first time in Egypt from a rust sample collected from a Hindi variety of wheat grown at Desouk, Fouadieh.

* Substance of a paper presented at the Second Conference of Wheat Breeding in the Near East, held in Cairo during March 13–18.

In 1952 race 17 was also the predominant race. Race E_1 appeared again and was isolated from a rust specimen collected from the variety Giza 139 grown at Behtim Farm of the Royal Agricultural Society.

It is desirable to demonstrate here that race 17 was isolated from all the rust specimens which were collected from several varieties of wheat grown in Cyprus and which were sent by D. K. Jones. Race 19 was isolated from one of these specimens.

It can be concluded that twelve physiological races of *Puccinia graminis tritici* Eriks. and Henn. were found thus far in Egypt. They are races 17, 19 21, 42, 14, 9, 24, 59, 88, 53, 123 and E_1, arranged according to their prevalence.

Reaction of wheat varieties to different races. In this study a great number of wheat varieties and strains produced locally or imported from other countries were tested for their reaction to the most prevalent races. In 1949 about 237 varieties were inoculated in the seedling stage with races 14, 17, 19, 21 and 42. It was found that fifty-nine varieties are resistant to these five races; forty-nine resistant to some of them and susceptible to the others; and 129 susceptible to all five races.

In 1950 about thirty-seven varieties and strains of wheat were tested, and the results obtained show that twenty of them are resistant to races 9, 14, 17, 19, 21 and 42 of wheat stem rust, thirteen resistant to some of these races and susceptible to the others, and four susceptible to all of these races.

During 1951 about seventy-four varieties and strains of wheat were inoculated with races 17, 19, 21, 24 and 42 in the seedling stage in the greenhouses, as well as in the adult stage in the rust nursery. The seedling stage reaction showed that forty-three of these wheat varieties were resistant to the above-mentioned races, sixteen resistant to some races and susceptible to the others, and fifteen susceptible to these races. In the adult stage it was found that all the varieties and strains which were resistant in the seedling stage retained their resistance in the adult stage except the variety Bobin-Gaza-Bobin, which was moderately susceptible. On the other hand, all the susceptible varieties in the seedling stage were also susceptible in the adult stage except one line of a cross between Giza 139 and *N.A.* 480, which was resistant in the adult stage.

In 1952 about sixty-six varieties and strains of wheat were tested for their reaction to races 9, 14, 17, 19, 21, 59 and E_1 in the seedling stage. It was found that forty-two were resistant to these seven races; nine resistant to some of them and susceptible to the others; and fifteen susceptible to all seven races.

From the reaction of this large number of varieties and strains of wheat to races 9, 14, 17, 19, 21, 42 and E_1, and the number of susceptible varieties to each race, it can be concluded that race 9 is more virulent than the other races, followed by races 21, 17, 19, 14, 42, 59 and E_1, arranged according to their relative virulence.

It is worth mentioning in this respect that the majority of the strains which showed resistance in the above-mentioned investigation were promising lines produced locally by hybridization with some of the introduced varieties. This is in contrast with the large number of these introduced varieties which were highly susceptible under Egyptian conditions, and as such were discarded from the breeding programme.

STRUCTURE OF AIR-DRY SODIUM THYMONUCLEATE

By Dr. U. W. ARNDT and Dr. D. P. RILEY

Royal Institution, Albemarle Street, London, W.1

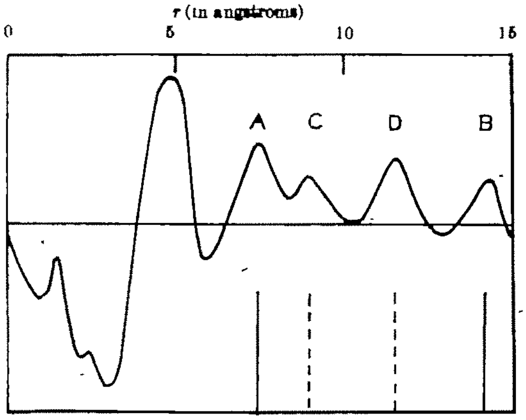
RECENT stereo-chemical considerations[1,2] and X-ray investigations[3,4] on the structure of deoxyribose nucleic acids have established with a fair amount of certainty that the structure of the polynucleotide chain is a helical one, with the phosphate groups lying on the outside of the helix and the flat sugar and base groups pointing towards the central axis. The diameter of the helix on which the phosphate groups lie is estimated to be about 20 A. It seems likely that the complete molecule is made up of two such helices coiled about a common axis.

Experimental studies which confirm this model have so far been confined to specimens having as high a degree of order as possible and which. therefore, have a high water content. We have thought it interesting to investigate whether any information could be derived from nucleic acids in the form of their sodium salts in an air-dry amorphous condition (c. 30 per cent water-content by weight) by studying their radial distribution curves. The amount of information obtainable in this way is necessarily much more limited than that afforded from oriented specimens or even from cylindrical Patterson functions and is less capable of a unique interpretation.

When a radial distribution curve is derived from the X-ray scattering curve produced by an unoriented specimen in the usual manner[5], the resultant function shows a multitude of peaks characteristic of all possible interatomic distances. When the substance investigated is a complex one in which the great majority of the atoms in the structure have similar atomic numbers, as for example in a protein, it is generally not possible to obtain any direct information from the radial distribution curve owing to its complexity. Significant results can, of course, be obtained in many cases by means of a comparison of the experimental radial distribution curve calculated from a detailed model.

The situation becomes more advantageous when the molecule under investigation contains some atoms, or groups of atoms, much heavier than the remainder, and when these groups are suspected to be arranged in a regular manner in the structure. The weight of interatomic vectors in a radial distribution function, as in a Patterson function, is the product of the number of electrons in the pair of atoms, and peaks corresponding to the distances between heavy groups can be expected to stand out and be capable of identification.

In the sodium nucleates the group $NaHPO_4$ can fulfil this role. This group is approximately tetrahedral in shape with the phosphorus at the centre of the tetrahedron, and it seems permissible to identify the prominent peaks in the experimental radial distribution curve with vectors between phosphorus atoms. The function $\Phi(r)$ plotted in the accompanying diagram is the smoothed radial distribution function calculated from the experimental scattering curve from sodium thymonucleate (calf) in the solid, air-dry state after multiplying the latter by an artificial 'fade-off' or temperature factor $\exp(-Bs^2)$, where $s = 4\pi\sin\theta/\lambda$ and $B = 0{\cdot}1$. The effect of this factor is to suppress the less prominent peaks in the distribution function. A curve calculated without the



Radial distribution curve from air-dry sodium thymonucleate

aid of this device (not reproduced) shows the same main features in the range 0–15 A. At values of r greater than 15 A. the smoothed curve shows no prominent peaks with the exception of one at about 28 A.; but in view of the nature of the numerical Fourier inversion process employed, it is doubtful whether this has any reality or whether it is merely an artefact.

The first peak at 1·45 A. agrees well with the distance between nearest neighbours in any organic structure, while the second peak at about 2·6 A. may be regarded as a mixture of the average distance between second-nearest neighbours (c. 2·5 A.) and the P—Na distance in the phosphate group (c. 2·9 A.). If the two-helix hypothesis[3] is adopted, the number of possible ways of interpreting the next peaks as intra- and inter-helix peaks is very limited. There is no way of coiling a polynucleotide chain in such a way as to make the nearest neighbour intra-helix vectors 5 A. and at the same time to make the second-nearest neighbour vector coincide with one of the following peaks. If one of the peaks at a value of r greater than 7·4 A. is assumed to represent the first intra-helix vector, too large and open a molecule would result and, in fact, the only reasonable combination of nearest and second-nearest neighbour P—P vectors is obtained by making these the peaks A and B, respectively, at 7·4 A. and 14·3 A. Considerable latitude exists in the dimensions of a helix to fit these values, but it cannot be outside the following limits:

Radius of helix = 11 ± 1·5 A.
No. of residues per turn = 11 ± 2
Fibre-axis repeat per residue = 2·4–3·4 A

Interpretation of the 5-A. peak as being the closest approach between helices 1 and 2 would explain the 9-A. peak C as being due to the vectors from a phosphate group on helix 2. The objections to this model are that the prominent peak D at 11·5 A. cannot then be interpreted and that the fibre axis component of the interchain distance would be only 4·45 A.

Alternatively, the position of helix 2 can be chosen so as to interpret peaks C and D as the vectors from phosphate groups on helix 1 to the nearest and second-nearest phosphate groups, respectively, on helix 2. The fibre-axis separation between the two helices is then 8·5 A. and becomes approximately a quarter to a third of the fibre-axis repeat. The prominent 5-A. peak must now be due to the combination of a large number of vectors between lighter atoms. This assumption seems justified, since the radial distributions of many organic polymers not containing heavy atoms, for example, globular proteins, β-proteins and collagen[7], and nylon[8a], 'Perspex'[8b] and cellulose[8c] have a peak in this region. It should be noted that this peak is of a different height from peaks A, B, C and D, while the P—P vectors in a long molecule would all have the same weights. In the diagram, the full lines are the intra-helix P—P vectors and the broken lines the inter-helix vectors calculated for a helix of radius 10·6 A. with ten residues per turn of 34 A. The second helix is displaced by 8·5 A. along the axis relative to the first in such a way as to make the inter-helix vectors as short as possible. In this model the line joining the two phosphorus atoms on the two helices which are pictured as being bridged by their bases[3] is inclined to the horizontal at an angle of about 15°, the two phosphate groups being 21 A. apart.

The above arguments alone do not uniquely define a specific model; we have not, for example, examined in detail a model of the kind proposed by Pauling and Corey[9] in which the phosphate groups lie near the core of the cylindrical molecule; it would appear that such a molecule would show little except a strong peak at 5 A. Nevertheless, it is of interest that an easy interpretation of the radial distribution function of amorphous air-dry sodium thymonucleate is possible which is in good agreement with the molecular model derived for crystalline nucleic acid.

We wish to thank Prof. J. A. V. Butler and Mr. P. F. Davison for the sample of nucleic acid. The investigation was supported by a grant from the British Empire Cancer Campaign. [Sept. 8.

CIS-TRANS ISOMERIZATION AND THE CEILING TEMPERATURE PHENOMENON IN POLYMERIZATION

By Prof. F. S. DAINTON and G. M. BRISTOW
Chemistry Department, University of Leeds

It has been shown previously that the rate of any addition polymerization process should ultimately decrease as the temperature is increased whatever the nature of the dependence of the rate on temperature at low temperatures, provided that the reaction is associated with a decrease in heat content and entropy. Moreover, the reaction-rate should become zero at a 'ceiling' temperature T_c, which is independent of the rate or chemical nature of the initiation reaction. This and related phenomena are due to the reversibility of the propagation reaction, which may be written:

$$m_1 + m_j^* \underset{k_d}{\overset{k_p}{\rightleftharpoons}} m_{j+1}^*, \qquad (1)$$

here m_1, m_j^*, $k_p = A_p \exp(-E_p/RT)$ have their ual significance and $k_d = A_d \exp(-(E_p - \Delta H)/RT)$, e subscript d denoting depropagation (that is, the verse of propagation), and ΔH is the heat of polyerization. The value of T_c is then given by:

$$T_c = \Delta H/\Delta S = \Delta H/(\Delta S^\circ + R \ln [m_1]) = \Delta H \Big/ \left(R \ln \frac{A_p[m_1]}{A_d}\right), \qquad (2)$$

here ΔS° is the value of the entropy change accomanying reaction when the monomer concentration 1 gm.-mol./litre. Polymerization systems exist in hich all these expectations may be realized.

It is of interest to extend this theory to the polyerization of 1,2 disubstituted olefines which can ist in geometrically isomeric forms. The isomers ill possess different ceiling temperatures, the fference between them at $[m_1] = 1{\cdot}0\ M$ being:

$$(\Delta H^{cis}/\Delta S^{\circ\,cis} - \Delta H^{trans}/\Delta S^{\circ\,trans}).$$

the special case where the polymers formed from the two monomers are identical, consisting of the same mixture of optical isomerides, two further possibilities arise. First, if the polymers have similar solution properties in each reaction mixture, we may write:

$$T_c^{cis} - T_c^{trans} = \left[\frac{\Delta H^{cis}}{\Delta S^{cis}} - \frac{\Delta H^{cis} + H^{trans} - H^{cis}}{\Delta S^{cis} + S^{\circ\,trans} - S^{\circ\,cis}}\right], \qquad (3)$$

and the ceiling temperature of one isomer can be predicted from that of the other provided the differences in heat content and entropy of the isomers are also known. Secondly, since the finished polymer molecules are identical, the growing polymer chains, ionic or free radical, derived from each isomer must also be identical, and it follows that on depropagation these radicals may produce either isomer. From general thermodynamical considerations, it is obvious that the isomers so produced must be in amounts corresponding to equilibrium under the prevailing conditions. Hence at temperatures where depropagation is occurring to any appreciable extent, the polymerization of an initially pure isomer should be accompanied by detectable isomerization. Embodying these processes in equation (1), we obtain equation (4):

$$cis\ m_1 + m_j^* \underset{k_d^{cis}}{\overset{k_p^{cis}}{\rightleftharpoons}} m_{j+1}^* \underset{k_d^{trans}}{\overset{k_p^{trans}}{\leftrightharpoons}} m_j^* + trans\ m_1, \qquad (4)$$

and the initial isomerization-rates of the pure *cis* and *trans* monomers will be $k_d^{trans}\,\Sigma[m_j^*]$ and $k_d^{cis}\,\Sigma[m_j^*]$, respectively. The isomerization should thus be detectable at those temperatures where the polymerization deviates appreciably from the Arrhenius law, and should increase with temperature according to the normal Arrhenius law, that is, show no ceiling temperature.

We have recently tested these predictions by determining the variation with temperature of the rates of interpolymerization of sulphur dioxide with *cis* butene-2 and *trans* butene-2, respectively, and the rates of the concomitant isomerizations. In these systems the monomers concerned may be loose 1 : 1 molecular compounds of the respective olefine and sulphur dioxide. The main conclusions are illustrated in Figs. 1 and 2.

The ceiling temperatures of the *cis* and *trans* butene-2 polymerization reactions at the same mol. fraction of olefine (0·091) are 35·7° and 32·5° C., and are independent of the nature and rate of the initiation process. Above about 25° C. both reactions are accompanied by measurable isomerization, the rate of which increases rapidly with temperature. Above the ceiling temperature for polymerization, the isomerization occurs rapidly and is, of course, unaccompanied by formation of high polymer; but no isomerization takes place if sulphur dioxide is absent or if, with sulphur dioxide present, the polymerization catalyst is absent or the system is not illuminated. The theoretical predictions would thus appear to be substantially borne out in practice; but, as will be shown elsewhere, when the full details of methods and results are published, there are reasons for believing that the polymer radical formed from *cis* butene-2 may not be precisely identical in stereochemistry with that formed from *trans* butene-2. This restriction introduces only a minor alteration to the theory represented by equation (4).

We are greatly indebted to Dr. K. J. Ivin for frequent discussions, and to the Department of Scientific and Industrial Research and the Anglo-Iranian Oil Co. for financial aid. [May 16.

Fine Structure in Polyethylene Terephthalate Fibres

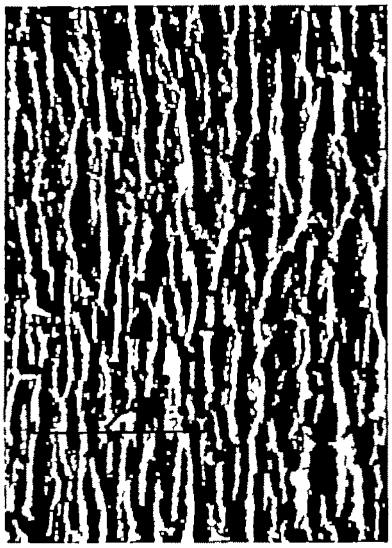
It has recently been shown by Kassenbeck[1] that drawn fibres of polyethylene terephthalate possess a surface skin, some 2500 A. in thickness. This was demonstrated by making two-stage polystyrene–silica replicas of carefully prepared sections, and photographing the replicas in the electron microscope. Kassenbeck also found that a replica taken from a region of a fibre from which the skin had been fortuitously removed revealed an unmistakable fine structure of oriented fibrils[2]. The apparent diameter of these fibrils varied between about 250 A. and 750 A.

It seemed to us desirable to follow up this work, and in particular to devise a reproducible technique for exposing the internal fine structure of drawn monofilaments. Working with comparatively thick monofilaments (0·25 mm. or more in diameter) we have succeeded in doing so.

The method consists simply in tearing open the monofilament down its length. It was thought at first that artefacts introduced by tearing might obscure the fundamental structural features of the specimen, but all the internal evidence suggests strongly that this does not happen. The structure dictates the direction which the tearing shall take, guiding it along planes of comparatively low cohesive strength, and thus the structure is revealed rather than obliterated.

For replication of the exposed surface, we used the evaporation technique, with germanium as the replicating medium. The evaporation method is simpler than that employing polystyrene and silica, as it involves only one stage: and germanium has the advantage over most of the more common replica metals that it yields completely amorphous films and does not tend to crystallize in the electron beam[3].

The accompanying photograph shows the structure revealed by this method in a drawn polyethylene terephthalate fibre. There can be little doubt of its essentially fibrillar character. The diameters of th fibrils appear to lie between about 200 A. and 1000 A and there are several of the larger fibrils which seem to be built up of those of diameter about 200 A. This suggests that the 200-A. fibrils might be th fundamental ones, and also that there might be a upper limit, indicated by the 1000-A. fibrils, to th extent to which the fundamental fibrils can conveniently group together.



It must be pointed out that any replica techniqu inevitably introduces some uncertainties regardin the absolute dimensions of the original, and th figures quoted above are therefore only approximat The results so far obtained are of qualitative, rathe than quantitative, significance.

We wish to acknowledge our indebtedness to D P. Kassenbeck for his generosity in discussing h results with us prior to publication. It was as direct result of this that we turned our attention t the internal, rather than the external, structure polyethylene terephthalate fibres. We also wish t express our thanks to Imperial Chemical Industrie Ltd., for permission to publish these results.

Resistant Membranes from Wool and Hair Fibres

In an investigation of the histological structure wool and hair fibres, we have used the followin technique in the preparation of sections for electro microscope examination. Sections 0·4–2·0 μ thickness were cut of peracetic acid-treated fibre embedded in ester wax[1]. The ribbons were tran ferred to water containing a little ethoxy-eth alcohol on a microscope slide; the slide was dried 35° C., and the wax removed with hot xylene. Th sections were treated with sodium hydroxide solutio for 5–10 min., and the slide was then washed car fully with distilled water, dried, and flooded with 0·3 per cent solution of nitrocellulose in amyl acetat The treated sections were then stripped from th slide on the nitrocellulose support, collected an examined.

Fig. 1 is an optical micrograph of a transvers section (stained with methylene blue) of peracet acid-treated wool after 10 min. in $2N$ sodiu hydroxide solution. The boundaries of the cortic cells, the nuclei of the cells, and some fibrils we resistant to the treatment. Fig. 2 is an electro micrograph of a transverse section of peracetic aci treated wool after treatment for 5 min. with sodiu hydroxide solution. From the electron microgra it can be seen that the resistant boundaries of th cortical cells are very thin membranes which hav fallen on their sides. The membranes are crease and have some fibrils adhering to them. The exam ination of shadowed specimens has shown that th membranes are of the same order of thickness a

the epicuticle[2], c. 100 A. We have observed similar membranes on electron micrographs of sections of air from a cow's tail and rat's hair which had been given the same treatment.

Peptic digestion of sections of peracetic acid-treated fibres, and the action of 1 per cent sodium ulphide solution at 60° C. for 3 hr. on untreated fibre sections also isolated these membranes.

We wish to thank Dr. R. L. Elliott and Dr. F. Happey for their interest, the Bradford Dyers' Association, Ltd., for a fellowship (to B. M.), and the Wool Textile Research Council for a scholarship (to M. S. M.). A more detailed account of this work will be published elsewhere.

Degree of Polymerization of Deoxyribonucleic Acid

The improvement of methods for isolating cell nuclei requires the establishment of suitable criteria of nuclear intactness which may be used to evaluate changes in technique[1]. The following experiments were performed in the course of an effort to devise methods for following changes in the degree of polymerization of deoxyribonucleic acid during nuclear isolation.

The physical properties of purified deoxyribonucleic acid vary widely, depending on the preparative techniques employed[2-4]. Poor reproducibility of viscosity measurements has been obtained on duplicate preparations from the same material[5].

A number of investigators have shown that the viscosity of deoxyribonucleoprotein solutions in strong saline is characteristic of deoxyribonucleic acid and is relatively uninfluenced by the proteins present[2,6]. In the hope of establishing a reference value for the viscosity of deoxyribonucleic acid which might be characteristic of the degree of polymerization of this substance in living cells, homogenates were rapidly prepared in cold 0·14 *M* sodium chloride and then mixed with strong salt solutions to dissociate the deoxyribonucleic acid from the proteins present and to give the characteristic viscosity.

Purified highly polymerized deoxyribonucleic acid has generally been studied in concentrations of about 0·2 per cent. However, when rat thymus was prepared so that the concentration of deoxyribonucleic acid was approximately 0·2 per cent after dilution with strong saline, the observed viscosity was so high that the solutions could not be pipetted. In order to get reasonable viscosities, thymus homogenates were prepared in concentrations of 1–2 per cent (wet weight/vol.) in 0·14 *M* sodium chloride and strained through bolting silk. Generally, 5-ml. aliquots were rapidly mixed with 10 ml. of 1·5 *M* sodium chloride to give viscous solutions containing about 50–100 μgm. of deoxyribonucleic acid per ml. as measured with diphenylamine. Other dilutions have also been studied. Viscosities were measured in size 200 Ostwald–Cannon–Fenske viscometers at 25° C. and are expressed as relative to controls pre-treated with crystalline deoxyribonuclease.

Fig. 1 shows the results obtained with thymus homogenates prepared in several concentrations from ten rats. Since the viscosities in all preparations increased on standing, the values used are the averages of a series of determinations made at regular intervals. It is noteworthy that solutions containing only 0·3–0·7 per cent wet thymus tissue (0·005–0·01 per cent deoxyribonucleic acid) have viscosities of the same order of magnitude as has been reported for 0·1–0·3 per cent solutions of purified deoxyribonucleic acid. The results obtained here suggest that reproducible results may be obtained using this method.

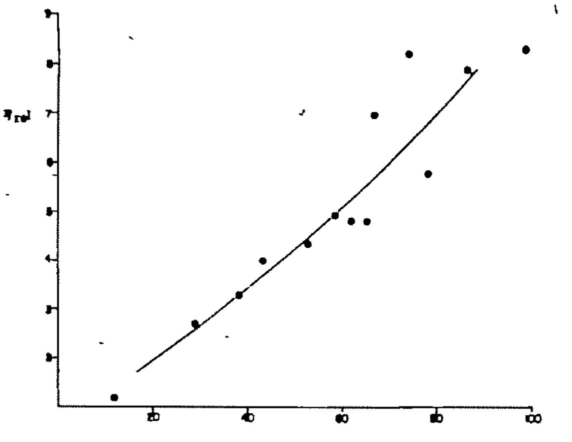

Fig. 1. Viscosity of thymus homogenates in 1 *M* sodium chloride. Viscosity is expressed as relative to control treated with deoxyribonuclease

Trypsin, chymotrypsin and urea (4 *M*) were all found to *increase* the observed viscosity, possibly by releasing a small additional amount of deoxyribonucleic acid. Further studies with preparations from kidney, spleen, liver and brain gave values which were similar for similar concentrations of deoxyribonucleic acid and were all slightly higher than thymus preparations. Within the limits of the technique used, the degree of polymerization of deoxyribonucleic acid in somatic tissues (except thymus) appears to be rather constant.

These observations are compatible with the view that the native substance exists in the form of extremely long chain polymers which are very easily broken. Thus, in the absence of salts, the high mutual repulsion along the molecule together with local fluctuations in thermal energy are thought to cause rapid spontaneous depolymerization. This is believed to account for the low molecular weights of preparations made with solutions of low ionic strength[4]. Treatment of a highly viscous fresh preparation in the cold with the Waring blendor for as short a time as 5 sec. causes an almost complete irreversible loss of viscosity. It is suggested that the purified 'highly polymerized' deoxyribonucleic acid, which appears to have a molecular weight[7] of 1–1·3 × 10^6, represents the *stable chain-length* capable of surviving the isolation procedure. The intact molecule is believed to be longer by some factor which cannot be evaluated as yet but which may be as high as 20. It is considered unlikely that an increase in polymerization takes place during preparation, since the homogenates were maintained at low temperature, were mixed with strong saline within 5–10 min. after the death of the animal, and produced a high viscosity within 2–3 sec. after mixing.

These experiments will be described in detail elsewhere; they were carried out under Contract No. W-7405-eng-26 for the Atomic Energy Commission. I acknowledge the technical assistance of Mary Lloyd Anderson.

Presence of 2-Carboxy-pyrrole in Mucoproteins and its Relation to the Viral Enzyme

2-CARBOXY-PYRROLE has been found as a hitherto unidentified component of mucoproteins. The presence of this component suggested itself from Odin's observation[1] that many influenza virus hæmagglutinin inhibitory mucins produce a purple colour, even without alkali pretreatment, on heating with the *p*-dimethylaminobenzaldehyde reagent. His findings have been extended to the prosthetic group of the pure inhibitory urine mucoprotein[2], the homogeneo inhibitory mucoproteins from human saliva[3], bovi and sheep submaxillary glands[4], the non-inhibito pure mucoprotein from human plasma[5], the no. inhibitory ovomucoid[6] and the proteins casein ar ox-serum albumin.

Authentic 2-carboxy-pyrrole was synthesized a cording to Oddo[7]. Bovine submaxillary mucoprote served as a source of the compound reacting direct with *p*-dimethylaminobenzaldehyde. The compou was separated from the protein by mild hydroly with barium hydroxide and extracted with absolu alcohol. Its identity with 2-carboxy-pyrrole w shown by the following comparisons. (1) Both ga very similar purple colours with *p*-dimethylamin benzaldehyde instantly in the cold, and for both t ninhydrin and Molisch reactions were negativ (2) Paper chromatography, using phenol, phen ammonia, butanol/acetic acid, *s*-collidine ar butanol/pyridine/water as solvents and Ehrli reagent as spray, revealed identical R_F values ar colour shade for both substances. The R_F values above order were 0·78, 0·64, 0·93, 0·42 and 0· respectively. (3) Reduction of the material wit Adam's catalyst and hydrogen yielded a substan which coincided with DL-proline in R_F value an colour when run in the solvents mentioned usi isatin as spraying agent.

2-Carboxy-pyrrole, ninhydrin-negative and unstab to acid, cannot be the ninhydrin-positive amino-ac of Minagawa[8].

It has been previously shown[9] that in the compou liberated from an inhibitory mucoprotein by the vir enzyme a non-amino-sugar is present; furthe Odin's observation[1] that this compound reacts directl with *p*-dimethylaminobenzaldehyde was confirmed.

It is suggested that in the prosthetic group of a inhibitory mucoprotein the carbonyl carbon of carboxy-pyrrole forms an amide link with the nitroge of an adjacent hexosamine, whereas the pyrro nitrogen engages in a glycosidic linkage with a sug residue. Both such linkages would be alkali-labile, they were indeed found to be. The pyrrole nitroge has no basic property; hence, if the viral enzyme an amidase, its action on the link mentioned will ad a positive charge to the residual mucoprotein n counterbalanced by an equivalent loss in the spl product. In fact, it has been recently found[10] b electrophoretic studies that the net negative charg of the inhibitory mucoprotein sharply decreases aft virus treatment. Thus the new data necessitate re-interpretation of some earlier findings[9].

I wish to thank Dr. K. H. Pausacker, University Melbourne, for valuable advice, and Dr. R. J. Winzle Los Angeles, for a generous gift of the homogeneou mucoprotein from human plasma.

Nucleotide Analysis on the Cyto-Scale

It is now possible to isolate and determine quantitatively the ribonucleic acid from individual nerve cells[1,2]. As ribonucleic acid can no longer be considered to be a tetranucleotide structure, methods for nucleotide analysis are of great interest. Thus, the composition of ribonucleic acid has been found to vary in different organs and even within the cell[3]. It takes a very active part in the different functional phases of the individual cell[4]. A knowledge of its purine–pyrimidine chemistry during these phases could therefore be expected to throw some light on the nature of its action. Existing methods for nucleotide analysis by paper chromatography[5] or ionophoresis[6] require amounts of ribonucleic acid in the range 100–1,000 μgm. For a more sensitive modification of these techniques, a few micrograms suffices[7]. Individual nerve cells contain 200–1,000 pgm. of ribonucleic acid (1 pgm. = 10^{-12} gm.)[2], or about one-millionth of that necessary by these methods. To permit analysis even of these small amounts the following method has been worked out.

A piece of copper silk is treated with alkali in order to produce swelling of its fibres. It is washed with water and immersed in a highly viscous citrate buffer of *p*H 3·6 containing glycerol and glucose. This buffer neither takes up nor gives off water at ordinary room humidity and temperatures, and is of high electrolytic strength. Its viscosity is 1,650 times greater than that of water. After at least 24 hours in this buffer the silk is taken out and the excess moisture removed by centrifugation. A fibre 1–2 cm. in length is stretched out on a quartz slide. Small dabs of paste containing the citrate buffer are smeared on both its ends. The quartz slide is then inverted over a groove in a thick glass slide with the fibre perpendicular to the groove. Hydrolysed ribonucleic acid (1 *N* hydrochloric acid for 1 hr. at 100° C.), from which the hydrochloric acid has been removed, is placed at some point along the fibre with a micropipette directed by a micromanipulator. It is applied slowly and is concentrated through the evaporation of the solvent. The work is controlled microscopically. When a suitable quantity of ribonucleic acid has been applied (100–1,000 pgm.), the chamber formed by the quartz slide and the groove is filled with liquid paraffin. Platinum micro-electrodes are then inserted into the dabs of buffer paste. A direct-current voltage (12 V./mm.) applied for two hours separates the four ultra-violet light-absorbing constituents of ribonucleic acid when the buffer has a viscosity of 1,650 centipoises. Less than 1 mm. of the length of the fibre is required, and several analyses can therefore be made simultaneously. The quartz slide is then removed from the oil chamber and provided with a quartz cover-glass. Liquid paraffin is used as the mounting medium. The fibre is photographed, together with a light-calibrating system, in monochromatic light of 257 and 275 mμ wave-lengths respectively. The plates are investigated photometrically and the absolute amount of each base and nucleotide can be computed.

An ionophoretic separation photographed at the two wave-lengths is shown in Fig. 1.

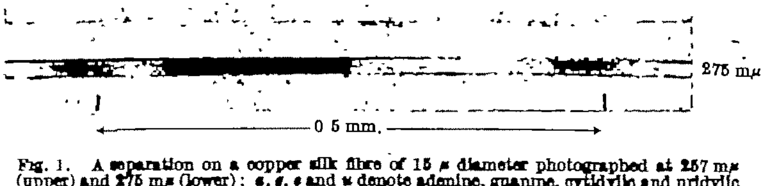

Fig. 1. A separation on a copper silk fibre of 15 μ diameter photographed at 257 mμ (upper) and 275 mμ (lower); *a*, *g*, *c* and *u* denote adenine, guanine, cytidylic and uridylic acid respectively

The method is a million times more sensitive than the conventional ones, and permits nucleotide analysis of individual cells.

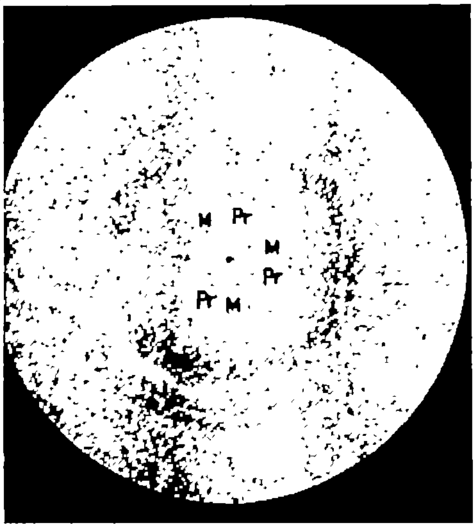
Identification of Amino-Acids Present in Purified Prothrombin by Circular Paper Chromatography

SEEGERS *et al.*[1] have very recently made an analysis on the amino-acid content, particularly tyrosine and tryptophan, of purified prothrombin. They have also shown by electrophoresis that their prothrombin preparation contains approximately 90 per cent of the protein in one component[1]. Several other workers[2-4] have investigated the nature of the protein in prothrombin. Astrup and Darling[4] have reported prothrombin to be a protein of globulin character. But the complete analysis of the prothrombin molecule with respect to different amino-acid contents is lacking.

In the present communication, the amino-acid composition of the purified prothrombin molecule has been determined by the circular paper chromatographic technique mainly developed by Giri and Rao[5].

Prothrombin was prepared from ox-blood by the method of Seegers *et al.*[6], and the activity of the prepared prothrombin found to be 1,800 units per mgm. protein nitrogen, as determined by the method of Ware *et al.*[7]. The nitrogen content of the preparation was found to be 13·36 per cent (micro-kjeldahl). The hydrolysis of the prothrombin molecule was carried out by autoclaving 100 mgm. of the dried prothrombin in 5 ml. of 6 *N* hydrochloric acid for a period of 6 hr. at 15 lb./sq. in. pressure. Excess hydrochloric acid was removed by vacuum distillation and lastly silver oxide was added to remove the last trace of acid. After filtration the filtrate was used for chromatography.

Chromatography was carried out on Whatman No. 1 filter paper of 18·5 cm. diameter in Petri dishes with solvent mixture containing butanol : acetic acid : water in the ratio of 40 : 10 : 50, the top layer being used. After the completion of the solvent run, the paper was air-dried and sprayed with a solution of 0·1 per cent ninhydrin in acetone and then heated at 60° C. for a period of 10–15 min. Amino-acids were



Circular paper chromatogram of amino-acids present in prothrombin. (*M*), Mixture of known amino-acids, (*Pr*), prothrombin hydrolysate

identified by comparing their positions with those of known amino-acids applied in a state of mixture and run on the same chromatogram. Multiple development[5] was found necessary for the complete separation of all the amino-acids. The following amino-acids have been found to be present in the prothrombin molecule: cystine, arginine, lysine, serine, histidine, aspartic acid, glycine, glutamic acid, threonine, alanine, proline, tyrosine, valine, methionine, phenylalanine and leucines. Tryptophan is also present in prothrombin as determined by us chemically; but it was not found in the chromatogram due to its destruction during acid hydrolysis.

The accompanying photograph shows the chromatographic pattern of the amino-acids identified in prothrombin.

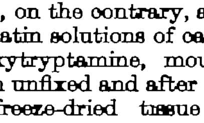
Detection of 5-Hydroxytryptamine in Mammalian Enterochromaffin Cells

IT is certainly well known that mammalian enterochromaffin cells acquire a golden-yellow fluorescence after fixation in formalin, as stated by Drs. Shepherd, West and Erspamer[1]. The views of the last author on their content of enteramine (5-hydroxytryptamine), based on his extensive researches into the enterochromaffin systems of Octopoda and Muricidæ as well as Amphibia and Vertebrata, have not been substantiated histochemically, however, and a considerable body of histochemical opinion holds alternative views. According to Cordier and Lison[2], the granules contained an *o*-diphenol with a short side-chain in the *para* position; Lison[3] maintains this opinion. Gomori[4] challenged this view, and concluded that a derivative of resorcinol (*m*-diphenol) was present. Lillie[5], applying his new diazosafranin test, agrees entirely with Gomori.

We are investigating the problem by means of a variety of histochemical and histophysical methods, and our conclusions, so far, support the hypothesis of Erspamer rather than those of Lison or Gomori, which, on the contrary, appear untenable. We have used gelatin solutions of catechol, resorcinol and of 5-hydroxytryptamine, mounted on microscopic slides, both unfixed and after formalin fixation. Formalin-fixed freeze-dried tissue containing the granules (mammalian duodenum) provided the histological controls.

The majority of reactions positive in the granules fail to distinguish catechol or resorcinol from 5-hydroxytryptamine; but the ultra-violet fluorescence is of critical significance. It is positive only in the granules, with unfixed resorcinol, and with fixed 5-hydroxytryptamine. Fixed resorcinols, that is, resorcinol-formaldehyde resins, unfixed 5-hydroxytryptamine and freeze-dried unfixed cells, do not fluoresce. The indole reaction, observed by Erspamer and Boretti[6] to be positive with enteramine, is negative with the granules and positive only with unfixed 5-hydroxytryptamine. It has been repeatedly stressed that the granules are a formalin artefact and, in view of the negative indole reaction in tissue sections, it is pertinent to inquire into the fate of 5-hydroxytryptamine after treatment with formalin. A reasonable explanation of this process is that a harmaline derivative of the type:



is formed. Such compounds do not give the indole reaction, but they are strongly fluorescent. It should prove interesting to compare their fluorescence spectra with those recorded for extracts of human carcinoid (enterochromaffin) tumours by Jacobson[7].

We are endeavouring to show not only that the enterochromaffin granules cannot contain a catechol or a resorcinol derivative and could contain a harmaline derivative, but also that the precursor of the latter is indeed 5-hydroxytryptamine. Work on these lines is proceeding and will be reported elsewhere.

Detection of Antigen–Antibody Interactions by an Interferometric Method

The most sensitive technique available for identifying proteins consists of using the protein, by injection into a suitable animal, as an antigen, and diffusing it through a gel containing the antibody produced by the animal. The antigen and antibody combine in certain proportions, and if they are present in sufficient amounts a band of precipitate is formed. Oudin[1] diffused one reactant into a gel in which the other reactant was evenly distributed. Ouchterlony[2] and Elek[3] diffused both components towards one another through a gel. Complex mixtures of antigens and antibodies may be analysed by means of this technique since each specific antigen–antibody system behaves independently as though the others were not present. The principles of the technique outlined below have been described by Ambrose[4] and the technique has been used by Conmar Robinson to examine the diffusion of solvents through polymers[5].

The apparatus consists, essentially, of two glass plates, each optically flat on one surface, which is silvered to give about 5 per cent transmission of light. The two plates with their silvered surfaces facing one another are placed horizontally on a microscope stage, with a cell containing a channel filled with gel between them, and the plates adjusted until they are almost parallel. The plates are illuminated from below with parallel monochromatic light the angle of incidence of which may be varied by means of an adjustable pinhole. Interference fringes are observed, each fringe being a contour line of constant optical path, which with a uniform medium is the path of constant distance between the silvered surfaces. The silver is given permanent protection by a glass plate in the form of a narrow wedge, with its upper surface optically flat, which is cemented to the silvered surface. The inclined upper surface of the protecting plate makes the secondary fringes formed by reflexions between it and the silvered surface of the other plate so close together that they do not interfere with the appearance of the main fringes. With suitable plates, a set of straight parallel fringes can be obtained. If in any region there is, for example, an increase in refractive index, the straight fringes will bend towards the apex of the wedge in that region in order to keep the optical path constant, since an increase in refractive index must be compensated by a shorter distance between the plates. Therefore, if there is an accumulation of a complex between an antigen and an antibody in a particular region, and if this results in a change of refractive index, an inflexion in the fringes should occur in which the peak corresponds to the point of equivalence of the antigen and antibody. This has been observed. The quantity of antigen and antibody combined before the commencement of precipitation may be estimated from the area under the peaks and the thickness of the gel, since the values for the refractive indices and specific refractive increments are almost constant for most proteins[6].

Photographs (*a*) and (*b*) show the fringe systems observed in a gel through which diphtheria antigen, *AG*, is diffusing from the left and antibody, *AB*, from the right. In photograph (*a*) a band of precipitate (B_1) has been formed on the right-hand side. In photograph (*b*), taken of the same system at a later stage, the band of precipitate (B_1) observed in photograph (*a*) has increased in width, and peaks in the fringes can be observed running across the channel to the left of B_1. These peaks (B_2) correspond to the point of equivalence of a second antigen–antibody system. No precipitate at B_2 could be detected when photograph (*b*) was taken. Before any precipitate had appeared in band B_1 it had the same appearance as band B_2 shown in photograph (*b*), giving peaks in the interference fringes, but being quite undetectable by other means.

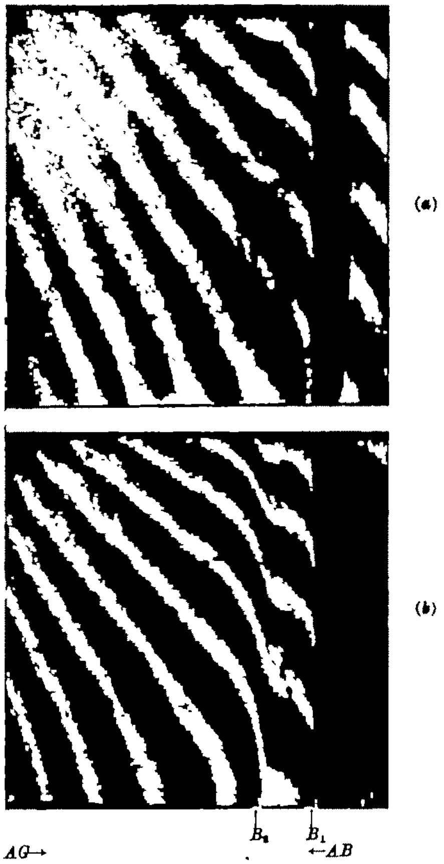

Fig. 1. Interference fringes showing specific precipitation of antigen–antibody complexes in gelatin

We wish to thank Prof. A. Haddow and Prof. F. Bergel for their advice and encouragement, and Dr. C. G. Pope for advice and supplies of diphtheria toxin and antitoxin, and also Mr. Menage for making the optical flats.

This investigation has been supported by grants to the Royal Cancer Hospital and Chester Beatty Research Institute from the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

Ventricular Nerve Cells in Mammals

Davies *et al.*[1] stated that: "It is widely believed that, in mammals generally, cardiac nerve cells are limited to the atria, extending at the most as far distally as the base of the ventricles near the atrioventricular sulcus", and they list an impressive number of orders, including primates, to which this statement applies. They found that only in Artiodactyla and Cetacea were ventricular nerve cells abundant, and they noted that in these the majority of the subepicardial neurons were unipolar or bipolar, with multipolar cells in a minority.

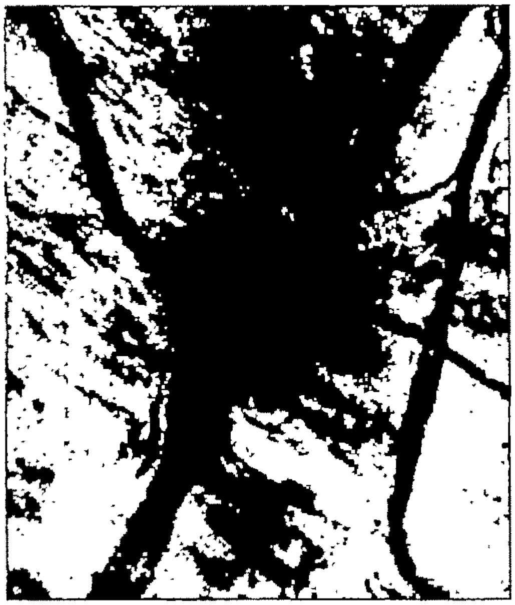

Fig. 1. Bundles of nerve fibres, with several adjacent ganglia, from the subepicardium of the left ventricle of *M. rhesus* (×86 combined intravital and supravital methylene blue)

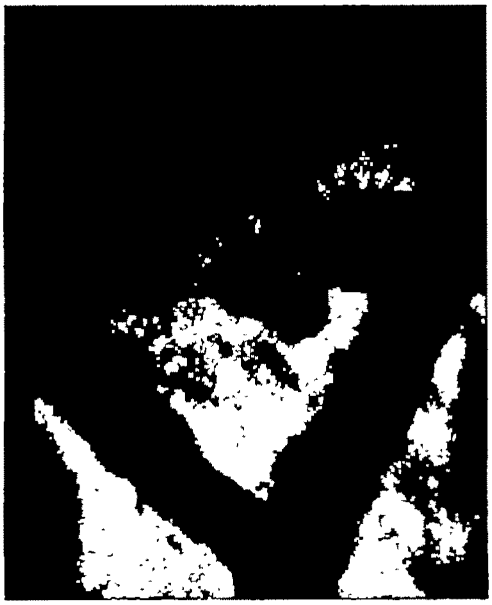

Fig. 2. Enlarged view (× 326) of one of the ganglia shown in Fig. 1

During investigations into intrinsic visceral innervation, using a combined intravital and supravita technique[2], we have found subepicardial nerve cell both in monkey (*Macacus rhesus*) and rabbit (*Oryctolagus*) material. In the monkey the ganglia wer numerous, and those illustrated (Fig. 1) were from subepicardial area nearer the apex than the atrioventricular groove, whereas in the rabbit the cell were scanty. The majority of the neurons are apparently multipolar (Fig. 2), and similar to thos occurring in other parasympathetic ganglia. If thi is confirmed, the common story that the ventricula supply is entirely or predominantly sympatheti may prove to be incorrect, at least in some primate

Quantitative Aspects of the Function of the Sympathico-Adrenal System

In a recent paper from this Department[1] th vascular effects produced by stimulation of sympathetic vasomotor fibres at different frequencie were studied and the 'normal' discharge-range o these fibres during 'resting' conditions and refle activation of the vasomotor centre was estimated The conclusion was that normally these fibres fir at very low frequencies (1–2 impulses per second) only exceptionally exceeding 6–8 impulses per secon even at strong reflex activation.

Motor effects produced by activity of the sympathetic nervous system are also effected by th suprarenal medullary discharge and, as a thir possibility, 'overflow' and consequently 'remot effects' of locally produced adrenergic transmitte substances may occur. In order to get furthe information about the quantitative role of the direc nervous control, the humoral effects of suprarena medullary discharge and overflow of the transmitte from sympathetically innervated regions, the following experiments were performed on cats.

The magnitude of the suprarenal medullar discharge, produced by maximal electrical excitatio at various frequencies of the nerve fibres running t the glands, was estimated by various biological tests The effects on the smooth muscles of the nictitatin membrane, the iris, the spleen and different vascula regions were quantitatively recorded.

Further, the direct sympathetic innervation o these effector groups was maximally stimulated a various frequencies within the 'physiological' discharge-range, and the responses obtained wer quantitatively compared with the effects produce by the discharge from the suprarenal glands an intravenously infused adrenaline and noradrenaline

Overflow of the adrenergic transmitter, release from a major tissue area, was induced by stimulatio at maximal rates of the corresponding sympatheti innervation. The remote effects produced by thi overflow were recorded on effector cells, such as th nictitating membrane, either normal or sensitized by previous denervation. In these experiments, too, the responses obtained were quantitatively compared with the direct effect of the normal sympathetic innervation, the suprarenal medullary discharge and further intravenously administered adrenaline and noradrenaline.

In another series of experiments an intense reflex activation of the sympathico-adrenal system was nduced by exposing the animals to controlled asphyxia. The motor responses of different effector groups were recorded as previously mentioned, and the role of the direct sympathetic innervation, the suprarenal medullary discharge and the 'overflow mechanism' was quantitatively analysed.

The results obtained allow the following conclusions:

(1) In the cat the upper limit of catechol secretion from the suprarenal glands, induced by stimulating the nerves running to the glands at maximal physiological frequencies, amounted to, roughly, 5 gamma per minute per kgm. of body-weight, when all the cells were concomitantly activated.

(2) The total amount of transmitter substances released at adrenergic nerve endings seems to be relatively small but, owing to the strictly local release in close contact with the effector cells, very high local concentrations are obtained giving effector responses generally ten or even twenty times bigger than those obtained by the suprarenal medullary discharge, when the glands were activated at similar discharge-rates.

(3) Overflow of the transmitter substances produces remote effects that are still smaller, being only about one-twentieth of the effects of the suprarenal medullary discharge and thus indeed negligible when compared with the effects induced by the direct sympathetic innervation. Further, remote effects can be recorded only on sensitized effector cells and then only at such high stimulation-rates that it seems very doubtful whether functionally significant overflow ever will occur in the intact organism.

It seems justified to propose that, as regards the motor function of the smooth muscle effector groups that are controlled by the sympathetic nervous system, these effector cells are quite dominated by their direct sympathetic innervation. Compared with this direct nervous control the motor effects of the suprarenal medullary discharge are quantitatively of minor importance, while the remote effects of transmitter overflow can be practically neglected. It then follows that, when evaluating the function of the suprarenal medulla, the chief stress must be laid upon the metabolic effects of its hormones, such as the mobilization of glucose from the liver and the lactic acid production in skeletal muscles. Such effects are pronounced even at a rather minute discharge from the suprarenal medulla, whereas they are poorly effectuated by the direct sympathetic innervation of the corresponding tissues.

Flight Muscle Autolysis and Reproduction in Aphids

BROADBENT[1], working with *Myzus persicae* (Sulzer) and *Brevicoryne brassicae* (L.), showed that there was a greater frequency of flights in batches of 1- to 4-day old alatæ than in batches of older aphids. I have now found that flight in these and other species of aphids is not possible after the first few days from the final ecdysis due to autolysis of the flight muscles. After they have lost the ability to fly the aphids may live for as long as 2–3 weeks, producing 1–4 larvæ per day.

Muscle autolysis may be readily observed by clearing the insects in clove oil, and is first detectable by the separation of the sarcostyles. I have observed it in alate alienicolæ of *Aphis fabae* Scop., *Myzus persicae* (Sulzer), *Brevicoryne brassicae* (L.), *Megoura viciae* Buckton, *Macrosiphoniella sanborni* (Gillette), *Acyrthosiphon pisum* (Harris) and *Macrosiphon euphorbiae* (Thomas).

Autolysis of the flight muscles has now been demonstrated in three widely separated groups of insects: ants[2], mosquitoes[3] and aphids, and it may occur also in some beetles[4]. The nitrogen from the breakdown of the flight muscles of ants and mosquitoes is thought to be utilized for egg production; muscle autolysis in aphids also appears to be associated with reproduction. Alatæ of *Aphis fabae*, whether they have flown or not, lose the ability to fly after the birth of 12–18 larvæ. These may be born within 2–3 days of the final ecdysis; but when reproduction was delayed by keeping the aphids off the plants for a few days except for short feeding periods, muscle autolysis was correspondingly delayed. Reproduction and muscle autolysis were also delayed by keeping the aphids on plants in complete darkness from the last larval instar.

Alatæ are economically important in infesting plants and spreading viruses for only a few days before flight is prevented by muscle autolysis. The number of plants that can be infested by a single alate aphid of *Aphis fabae* or similar species before it loses the ability to fly will depend upon the number of larvæ it deposits on successive plants. Aphids depositing only a few larvæ on each of the plants they visit may infest several, whereas those which deposit a large number of larvæ on the first plant on which they alight will be able to infest fewer afterwards.

This work is being continued.

I wish to thank Dr. C. G. Johnson for his many helpful suggestions.

Phase Coloration in Lepidopterous Larvæ

THE occurrence of 'phases' in the larvæ of Lepidoptera has been reported by Faure[1] and by Williams and Long[2]. Field observations have shown that in mass outbreaks of *Persectania ewingi*, the New Zealand armyworm, the larvæ were unusually dark, and this suggested the occurrence of phases in the larvæ of this insect.

This darker coloration has been reproduced in the laboratory by rearing larvæ under crowded conditions. The normal colour of the larvæ is a light reddish-brown, with dark brown or black dorsal stripes and dull red, white or black lateral stripes. The 'gregaria'—larvæ reared under crowded conditions—exhibited a range of colour from dark brown, through to dull black with red and white lateral stripes. The dark colouring became apparent very early in larval life, and third-stage gregaria were quite distinct from third-stage solitaria. These larvæ were reared on grass.

Further larvæ were used as test insects in the development of an artificial food, based on that developed by Beck and Stauffer[3]. There were no differences in colour between gregaria and solitaria. This food contained no pigments.

The theory tentatively suggested to explain these phenomena is based upon the greater activity observed in larvæ kept under crowded conditions. This activity is due not only to competition for food, but also to the tendency towards cannibalism which develops when larvæ are crowded together. It is suggested that there is an increased rate of metabolism consequent upon this greater activity, and that this results in the production of waste products in excess of the amounts which can be excreted. There is thus an accumulation of waste products in the body.

This theory is supported by the above observations if it is assumed that the accumulated waste products of larvæ fed on grass contained grass pigments. The artificial food contained no colouring matter, so that, although waste products accumulated in the bodies of the gregaria, they had no effect on larval colour. Further support is given to this theory by the fact that very dark gregaria, when removed to solitary conditions, slowly reverted to the normal solitaria colour, indicating that there was a steady excretion of waste products from the body under conditions of reduced activity.

Experiments using artificial food containing various pigments will be set up during the coming season. If the theory outlined above is correct, the colour of gregaria should bear some relation to the pigment incorporated in the food.

Lecithinase Activity of Chloroplasts

The low nitrogen/phosphorus ratio of phospholipids isolated from fresh carrot root or cabbage leaves has been shown to result from the loss of nitrogenous bases by enzymatic action during their isolation[1,2]. A preliminary attempt to extract phospholipids from spinach chloroplasts gave a product with a low nitrogen/phosphorus ratio, suggestive of similar enzymatic degradation. Although lecithinase activity has been investigated in a variety of plants[1–4], the occurrence of lecithinases in chloroplasts has not been reported before.

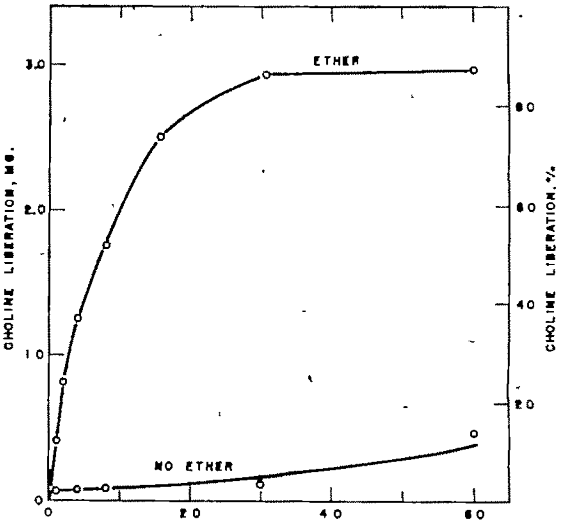

Fig. 1. Influence of diethyl ether on the enzymatic liberation of choline from lecithin by spinach chloroplasts. Reaction mixtures contained 0·5 ml. of 1 M acetate buffer (pH 4·7), 2·0 ml. of water, 0·5 ml. of 5 per cent lecithin emulsion and 2·0 ml. of chloroplast suspension (2·78 mgm. chlorophyll/ml. suspension), plus 10 ml. of diethyl ether for the 'ether curve'; temperature, 25° C.; reaction was stopped by addition of 0·1 ml. of 3 N hydrochloric acid; free choline in the aqueous phase was measured (ref. 8)

Leaf juices were fractionated by high-speed centrifugation[7] into cytoplasm and chloroplast fractions. Their lecithinase activities were measured by determining the formation of free choline[8] and phosphate[9] from pure phosphatidylcholine[10]. Buffered mixtures of chloroplasts and substrate liberated choline very slowly; however, by shaking the mixtures with diethyl ether, the rate of liberation was greatly increased (Fig. 1).

Choline-liberating activity of juices prepared from spinach, sugar beet or cabbage leaves was found to be associated entirely with the chloroplast fractions. The cytoplasm fractions had no activity and were inhibitory. These findings may explain the reported absence of lecithinase activity in spinach press juice[5] which probably corresponds to the cytoplasm fraction. With spinach or sugar beet chloroplasts the optimum pH for choline liberation was 4·7 in 0·1 M acetate buffer, while with cabbage chloroplasts the optimum was between 5·0 and 5·8 [3]. The choline-liberating activity of spinach chloroplasts was unchanged after 10 min. heating at temperatures up to 40° C., but decreased rapidly at higher temperatures, reaching a negligible value at 70° C. [1,2,3].

The initially rapid liberation of choline from lecithin by spinach chloroplasts (Fig. 1) was accompanied by a much slower liberation of both inorganic and water-soluble organic phosphates[3,4]. Similar formation of phosphates was observed with dipalmitoyl-L-α-glycerophosphoric acid (phosphatidic acid) as substrate. Inorganic phosphate was liberated from L-α-glycerophosphate, but phosphorylcholine and L-α-glycerylphosphorylcholine were unaffected. Thus, the primary step in the degradation of lecithin by chloroplasts appears to be hydrolysis to choline and phosphatidic acid[1,2,3]. Subsequent loss of phosphate and fatty acid from phosphatidic acid may account for most of the inorganic and water-soluble organic phosphate found[3].

Concerning the mechanism of ether activation, the following are noteworthy: (1) The rate of choline liberation increased rapidly with increase of ether to a maximum at ether-saturation, beyond which the rate remained constant. (2) At or beyond saturation, the lecithin and chloroplast phases were seen to coalesce. (3) Ether-extracted chloroplast suspensions still required the presence of ether for activation; no lecithinase activity appeared in the ether or aqueous phases. (4) Replacement of ether by 'Dreft' or acetone caused some activation, whereas butanol, dioxane, chloroform, petroleum ether, methanol or n-butyl ether produced little or no activation.

The finding that diethyl ether activates the lecithinases of chloroplasts supports the explanation given[2] for the origin of the phosphatidic acid isolated after ether extraction of cabbage 'cytoplasm'[11] (which probably contained chloroplasts), and limits the use of this solvent as an extractant for chloroplast phospholipids.

I am grateful to Dr. P. R. Gorham for stimulating discussion and advice, and to Dr. E. Baer for generous gifts of synthetic phosphatidic acid, phosphorylcholine and L-α-glycerylphosphorylcholine.

A New Method of measuring Oxygen consumed in the Metabolism of Small Animals

THE principle of replacing, by means of electrolysis, the oxygen consumed in measurements of metabolism offers the threefold possibility of having a high degree of sensitivity, of controlling the phenomenon for an unlimited time and avoiding calculation entirely. An electrolytic cell (30 per cent sodium hydroxide), capable of producing oxygen, is connected by means of a tube to the thermostatic chamber in which the animal is enclosed. The chamber is provided with a mechanical system for circulating the air and absorbing carbon dioxide, and comprises a pump and a purifier. The whole, including the metabolism chamber, the pump, the purifier, the bell-jar placed over the nickel electrode, and the connecting tubes, is hermetically sealed. Measurement and integration in time of the quantity of electricity supplied by the current generator to the electrolytic cell is done electrically.

The nickel electrode, immersed in the electrolyte, releases oxygen in quantities directly proportional to the electricity passing through it (Faraday's law); for example, 1 gm. atom of oxygen every 2 × 96·540 coulombs, independently of temperature or pressure.

If the oxygen released by the electrode is not consumed by the animal, it tends to produce excess pressure in the hermetically sealed enclosure in which it is developed. This will cause a decrease in the level of the electrolyte around the electrode and, consequently, a reduction in the area of immersed surface, with a relative curtailment in production of oxygen.

A similar and opposite auto-regulating effect occurs when the consumption of oxygen exceeds the quantity released; the consequent decrease in pressure causes the level of the electrolyte to rise, with a corresponding increase in the production of oxygen.

It is obvious that the rapidity and sensitivity of the system can be varied by regulating the angle of the electrode in relation to the surface of the electrolyte, its shape, nature, the total volume of the enclosure in which the gas is released, and so on. Since the quantity of oxygen released by electrolysis is dependent solely upon the product of current and time (ampere-hour), no error in measurement is brought about by possible fluctuations in voltage at the generator.

The measuring instrument can be readily calibrated in volumes of oxygen consumed by taking into account the electro-chemical equivalent, or in calories. In the latter case 1 litre of oxygen with a respiratory quotient of 0·8 is equivalent to 4·8 kcal., and the current per hour will immediately give the calories per hour consumed by the animal.

Using this method, the average heat production of the albino mouse was found to be 30 kcal./kgm.-hour, and that of the albino rat 15 kcal./kgm.-hour.

Patents on the apparatus are pending.

Chromosomal Inversions with Sex-limited Effects

FOR a long time it was thought that the *Drosophila* X-chromosomes were genetically very homogeneous. As one-third of the X-chromosomes in the populations are carried by the males in haploid condition, the X-chromosome genes are much more exposed to natural selection than the autosomic genes. Kerr and Kerr[1] have shown, however, that *D. melanogaster* X-chromosomes from natural populations carry a large amount of concealed variability.

The object of the present note is to present further evidence of the presence of X-chromosome variability due to gene combinations with sex-limited effects.

In the study of chromosomal variability of natural populations of *D. willistoni* and of *D. paulistorum*, X-chromosome inversions were found that present sex-limited effects.

Samples of natural populations of *D. willistoni* and of *D. paulistorum* were obtained from many regions of Brazil. The results of the analysis of these samples may be found in some papers already published[2,3] and in unpublished observations by Prof. Th. Dobzhansky and myself.

Single females of the samples were put in vials with culture medium. The salivary-gland chromosomes of a single F_1 larva from every female of the sample were studied. In two *D. willistoni* samples, those from Monjolinho[2] in the State of Goiaz and from Salvador (unpublished) in the State of Bahia,

Table 1. FREQUENCIES OF HOMOZYGOTES AND HETEROZYGOTES FOR TWO X-CHROMOSOME INVERSIONS IN TWO BRAZILIAN POPULATIONS OF *D. willistoni* AND TWO OF *D. paulistorum*

Origin of sample and chromosome studied	Homozygotes	Heterozygotes	Total	χ^2
D. willistoni				
Monjolinho	$DD + dd$	Dd		
XR	11	72	83	44·8
Salvador	$DD + dd$	Dd		
XL	46	77	123	7·8
D. paulistorum				
Cantareira	$CC + cc$	Cc		
XL	7	22	29	7·7
Sooretama	$CC + cc$	Cc		
XL	11	45	56	20·6

and in two *D. paulistorum* samples, those from Cantareira (unpublished) in the State of São Paulo and from Sooretama (unpublished) in the State of Espirito Santo, X-chromosome inversion heterozygotes were found with a frequency significantly higher than 50 per cent (see Table 1, where the deviations are calculated taking 50 per cent as the expected frequency of the heterozygotes).

As is well known, in panmictic populations, such as *D. willistoni* and *D. paulistorum* populations, inversion heterozygotes may have frequencies higher than 50 per cent only if the heterozygotes have adaptive values higher than that of both homozygotes.

The data presented in Table 1 show clearly that the X-chromosome inversions studied are heterotic. The heterotic value of the X-chromosome inversions can be manifested only in the females, the males being haploid for the X-chromosome. Genes with sex-limited effects must therefore be responsible for the heterotic value of the heterozygous X-chromosome inversions, as has been shown also by Wallace for the 'sex-ratio' gene arrangement in *D. pseudoobscura*[4].

The cytological data here presented show, from an aspect different from that studied by Kerr and Kerr[1], the importance of gene combinations with sex-limited effects in the genetics of natural populations of *Drosophila*.

These data give also further evidence of the adaptive value of chromosomal inversions in *D. willistoni* and in *D. paulistorum*.

Reconstitution of Virus X-Saturated Potato Varieties with Malachite Green

POTATO virus X is well known as a source of loss to the potato industry, and schemes exist to protect newer varieties from contamination. In most countries there remain in use – often in favour – varieties that are saturated with virus X. In Australia the varieties Brownell, Carman and Delaware are in this class. To free such a variety from virus X by chemotherapy would be a significant economic advance. It would also be of importance to the general problem of plant virus control by demonstrating that, even with a stable, mosaic-type viru like potato X, there is a sufficient difference betwee the biosynthetic processes of the virus and of th host to make selective chemical therapy a re possibility.

An attack on this problem was made usin the potato variety Early Carman. Limasset an Cornuet[1] showed that the content of tobacco mosai virus steadily decreases as the stem apex approached, so that the cap of meristem above th leaf rudiments contains very little virus. Takahash showed that the diaminotriphenylmethane dy malachite green, strongly inhibited the biosynthes of tobacco mosaic virus, apparently by enzym blockage. Assuming that these findings applie equally to virus X, the problem was to expose th extreme growing tips of potato stems to the actio of malachite green in such a way that maximu inhibition of virus multiplication occurred, but at th same time growth of the stem tip continued, so tha the apex might grow away from the virus. It wa decided to work aseptically in complete culture solution, and the stock nutrient of Phillip White[3] wa chosen. A bacteriologically sterile clone of Earl Carman potato was developed by removing a ste apex to agar culture medium and propagating th resultant plantlet vegetatively either on agar in tub or on filter paper slopes in liquid nutrient. Whe sufficient material had been developed, stem tip approximately 1 cm. long were added to flasks con taining 50 ml. of liquid nutrient plus malachite gree at concentrations of 1–4 parts per million, and allowe to float in the nutrient for three weeks. Some growt occurred. The tips of these stems, approximatel ½ cm. in length, were then transferred to new liqu nutrient without malachite green to recover and gro for testing by inoculation to *Datura stramonium* o *Gomphrena globosa*. Of the sixteen plants tha survived, one plant, from the series containin malachite green at 3×10^{-6}, proved to be free fro virus X. Others gave a positive test for virus only after some time had elapsed, indicating tha the virus X content had been reduced by treatmen to a very low level. All plants of the untreated con trol series retained a high content of virus X. Th malachite green seems to have exerted a true chem therapeutic effect.

The only instance of successful chemotherapy a plant virus so far reported is that of peach X-disea by Stoddard[4]. This virus showed every evidence instability. From the number of chemicals tha successfully inactivated it *in vivo*—a list includin calcium chloride and zinc sulphate—and from th fact that spontaneous recovery occurred among th control plants, one would doubt whether any tru chemotherapy was involved. The freeing of potat tissue from virus X by malachite green is, to m knowledge, the first instance of successful chem therapy of a stable mosaic-type virus.

A full account of this work will be publishe elsewhere.

Phase Transformation in Uranium

It is well known that pure uranium has three ystalline modifications. The two phases occurring the lower temperatures are α-uranium, which has n orthorhombic unit cell, containing four atoms[1], nd exists from room temperature to 660° C., and uranium, which has a tetragonal unit cell, containing thirty atoms[2], and exists in the range 660°–760° C. During an investigation into the crystallography of e β → α phase transformation of uranium chromium lloys at low temperature, the orientation of two plates was found relative to that of the β-grain om which they were being precipitated.

The specimen was a piece of 1·4 atomic per cent hromium alloy. This was heated *in vacuo* in the -temperature range, cooled slowly into the β-mperature range, and then quenched to retain latively strain-free polycrystalline β-solid solution[3].

After further heating in an oil-bath at 80° C. for several hours, microscopic examination disclosed hat several plates of α-phase had formed in the -grains, presumably by a martensitic process[4]. One -grain had in it two well-separated α-plates (Fig. 1), that it was possible, by using Cahn's microbeam -ray camera[5], to obtain Laue photographs from the -grain and both α-plates. Hence the orientations of the grain and plates were found relative to the urface plane of the specimen and a standard direction on the camera stage unit.

Since only a single surface on the specimen was sed, the poles of the habit planes of the α-plates ould not be identified by a direct method. However, he plane perpendicular to the intersection of a plate ith the surface of the specimen must contain the ole of the habit plane of that plate. This plane, ormal to the trace of the habit plane, was determined for each plate and plotted as a great circle n the stereographic projection of the α- and β-rientations.

The planes normal to the traces of the habit planes nd the orientations of the α-plates relative to a standrd (0,0,1) stereographic projection of the β-grain are shown in Fig. 2. This shows that, within the limit f experimental error, the (0,0,1) α-plane is parallel to a {8,1,7} β-plane, and the (0,1,0) α-plane is approximately parallel to a {12,3,4} β-plane. The calculated angle between the (8,1,7) β-planes and the $(\overline{12},\overline{3},4)$ -planes is 89° 28′. It is probable that the orientation f the α-plates relative to the β-grain is not quite the same as that of their original nuclei relative to the same grain, since both phases are deformed as the -plates grow[4]. However, this orientation difference hould not be more than a degree.

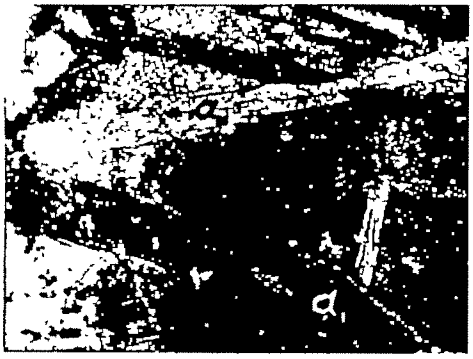

Fig. 1. Plates of α-phase formed in a β-crystal. The plates examined are marked α, and α,,. Polarized light. × 150

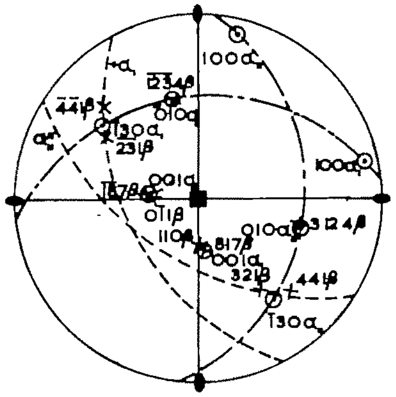

Fig. 2. ■, Pole of (0,0,1) β-plane; ●, pole of {1,0,0} β-planes; ×, pole of other β-planes; ○, pole of α-plane; ———, β-zone; —·—·—, α-zone; – – – –, trace normal of habit plane; α, and α,, first and second α-needles

Holden[4] reported that the habit plane for this transformation was the {3,2,1} β. Each plane normal to the trace of a habit plane contains a pole of this type of plane; but accidentally these trace normals are almost equivalent crystallographically, and hence if Holden's result were not known, the pole of the habit plane could be any pole in the trace normals. Such a pole is that of the {4,4,1} β-plane, and it is suspected from measurements on other specimens, where it has not been possible to obtain the orientation of the α-plates, that this may be another habit plane. Neither the {4,4,1} β-plane nor the {3,2,1} β-plane lies parallel to a rational plane in the α-structure; but it is interesting that both lie near a {1,3,0} α-plane, which is a prominent twinning plane for the α-phase[6].

A fuller account of this work will be published elsewhere.

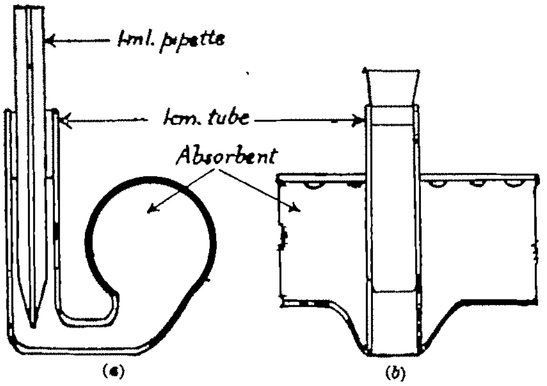
A Modified Pettenkoffer Tube

A modification of the normal Pettenkoffer tube has been developed to save time and materials and at the same time ensure accuracy in the estimation of carbon dioxide evolved during soil respiration experiments. It has also proved of use in the study of the respiration of *Aspergillus niger* in work at this Station by Dr. D. J. D. Nicholas.

This modification allows a 1-ml. sample of the absorbent, usually 0·1 N sodium hydroxide, to be withdrawn; hence the absorption of the carbon dioxide can be studied without frequent changing of the sodium hydroxide. The accompanying diagram shows this adaptation; half-way along the length of a normal tube, a second glass tube, J-shaped and wide enough to admit a 1-ml. pipette, is joined at its base and arranged at right angles to the main tube, its open end, closed by a rubber bung, lying above the level of the liquid in the main tube.



Modification to Pettenkoffer tube. (a) Transverse section of central portion of tube showing attached J-tube modification, with 1-ml. pipette being inserted for sampling. (b) Horizontal view of modification. Stopper inserted and gas bubbling through

A standard method was used as follows: (1) The bubbling of the gas through the sodium hydroxide in the main tube was stopped by means of a screw-down clip. The sodium hydroxide was thoroughly mixed by raising and lowering the tube twice. (2) The rubber bung of the side tube was removed; a 1-ml. sample of the sodium hydroxide was taken and the bung replaced. This sample was added to a standard 15 ml. of barium chloride (30 gm. $BaCl_2.2H_2O$ in 1,000 ml. water) containing one drop of phenolphthalein and immediately titrated against 0·01 *N* sulphuric acid.

It takes 15 min. only to sample and analyse twelve units.

Thanks are due to Mr. G. Jones for the glass blowing involved in the making of the apparatus and the Agricultural Research Council for permission to publish this note.

Investigation of Travelling Disturbances in the Ionosphere by Continuous-Wave Radio

OBSERVATIONS on the horizontal movements in the *F*-region of the ionosphere by radio methods using the pulse method of ionospheric sounding, and also by employing a precision direction-finding technique, have been made during the past few years[1-7]. The present communication reports the results of recent investigations on travelling disturbances in the ionosphere obtained by a new and simple method in which use has been made of the continuous-wave radio signals from a distant short-wave transmitter.

The investigations were carried out during June–November 1952. Use was made of the continuous-wave transmissions from Madras over a 640-km. path on frequencies of 9,590 kc./s. during afternoons and 4,920 kc./s. during late evenings and nights. Simultaneous observations on oblique-incidence pulse transmissions from Madras were also made during the hours of study to facilitate interpretation of the results. The oblique-incidence pulse observations show that during the afternoon hours, when the transmissions on 9,590 kc./s. are used, only the 1 × *F* and 2 × *F* modes are active and are of almost equ intensity, while during the late evening and nig higher-order modes up to 5 × *F* are present on frequency of 4,920 kc./s., the 1 × *F* and the 2 × being much stronger than the other modes.

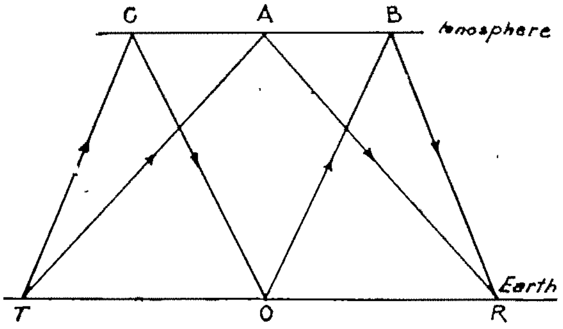

Fig. 1

The principle of the method is as follows. signals from a distant transmitter arrive at t receiver by way of more than one reflexion at t ionosphere, we have a number of points of reflexi at the ionosphere along the transmitter–receiver pat Taking the simplest case, when the signals arri by 1 × *F* and 2 × *F* modes, there are three equ spaced points of reflexion in the ionosphere—namel *B*, *A* and *C*, as shown in Fig. 1. If, then, a disturban travels horizontally along *BAC* with uniform velocit its effect on these transmissions will be observed the receiver on three occasions just when it cross the points *B*, *A* and *C* in succession. If the size this irregularity is larger than the distance *BA* *AC*, the curvature developed in the ionosphere the disturbance may include two of the points *A*, and *C*, or even all three of them. In either case, t fading record of the received signal will show Doppler fading similar to the one observed on ve high frequencies when an aircraft is moving overhea This case will be fully discussed in a future com munication. When the extent of the curvature smaller than the distance between any two poin of reflexion, it includes only one point of reflexi at a time, and the record of the received sign intensity shows an enhancement due to a focusi effect at the moment it crosses the point in questio Consequently, three equi-spaced peaks will obtained in the signal intensity record, the spaci between any two successive peaks being equal to *x*/ where *x* is the distance *BA* or *AC* and *v* the unifor velocity of the disturbance.

The foregoing principle has been applied to dedu the velocities of travelling disturbances in the ion sphere. A typical record illustrating the effe obtained is shown in Fig. 2. Oblique-incidence pul observations show that, during the hours of stud only the 1 × *F* and 2 × *F* modes are active. W may therefore expect three peaks in the record signal intensity, indicated by arrows, in Fig. 2. Fro several such records the velocities are deduced to

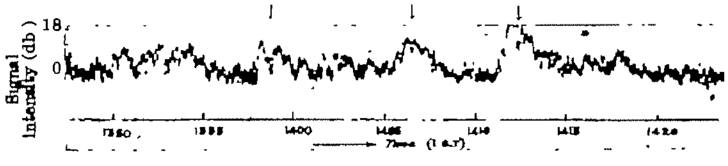

Fig. 2. Continuous-wave signal-intensity record showing the effect of travelling dis turbances in the ionosphere. Madras transmissions on a frequency of 9,590 kc./s (31 m.); July 17, 1953

in the range of 200–400 m./sec., which are consistent ith the values of 35–350 m./sec. given by Ross and ramley[1–3], while Munro's values are 100–200 m./sec. Day-time velocities are found to be higher than those at night. It is observed that the velocity does not main constant during the day, as revealed by the nequal spacing between the peaks, while it is fairly niform during the night. Since the 2 × F mode ffers two ionospheric reflexions and one ground flexion, the presence of this mode gives rise to me scattered signal at the receiver. This makes the eak corresponding to the point C in Fig. 1 appear iffuse. This feature may incidentally be utilized for educing the direction of travel of the disturbance. n the present case the deduced direction of travel of the disturbance is from north-north-east to south-uth-west.

The method has the advantage that the experi- ental arrangement is simple and inexpensive. A umber of recordings have to be made of transmissions rom different directions if one wants to study the iovements of the disturbances in all directions, thus miting to some extent the usefulness of the method.

Complete details of these investigations will be ublished shortly. I wish to thank the Station ngineer, All India Radio, Madras, for his co-operation in arranging the pulse transmissions from Madras.

Beynon, W. J. G., Nature, 162, 887 (1948).

THE method reported by Y. V. Somayajulu[1] for he investigation of horizontal movements of disturbances in the F-layer of the ionosphere utilizes transmissions from a distant short-wave transmitter. We have now evolved a method for a similar study of such travelling disturbances by recording simultaneously the signal-strength of continuous-wave transmissions from two distant short-wave transmitters radiating on frequencies which are very close o each other.

The principle of the method is as follows. When ontinuous-wave transmissions from two distant hort-wave transmitters, arriving at a receiving centre y way of a single-hop reflexion at the ionosphere, are tuned in two communication receivers and the ignal-strength variation recorded simultaneously, travelling disturbance passing over any one of the points of reflexion produces an enhancement of the ignal strength due to the focusing effect, and this will be noticed as a prominent peak in the record. If a travelling disturbance passes successively over both the points of reflexion, two almost identical nd prominent peaks will be noticed in both the records with a time-difference t equal to the time taken for the disturbance to travel the distance d between the two single-hop reflexion points in the onosphere. The quotient d/t gives the component of the velocity of the travelling disturbance along he line joining the single-hop reflexion points.

Continuous-wave transmissions from Calcutta and Dacca on the 41-m. band have been used in the present investigation for obtaining simultaneous records of the signal-strength variations of these transmissions received at Waltair during the afternoon, the usual continuous-wave recording equipment being used for this purpose. Light spots reflected from mirrors of the two recording galvanometers trace out the signal-strength variations side by side on the same photographic paper moving with a speed of 14 in./hr. The galvanometers have been suitably damped to eliminate fast-period fading, as the expected similarities are of a long-duration type. Hourly records were taken daily from 1200 to 1300 hr. over a period of two months during May–June 1953. Almost half the records thus obtained showed prominent peaks and curvatures in the Dacca record which reappeared in almost identical form in the Calcutta record after a definite time-interval of 8–13 min. A typical record obtained on June 13 is reproduced in Fig. 1. It can be clearly seen from this record that all the prominences a, b, c and the curvatures between them in the Dacca record, presumably produced by a single travelling disturbance, are reproduced almost identically but with a slight difference in amplitude in the Calcutta record after a constant time interval of 8·5 min., giving a value of 230 m./sec. for the velocity component of the travelling disturbance, the distance between the first-hop reflexion points being 120 km. Except for one or two cases for which high velocities are obtained, the values for the velocity components for most of the records range from 150 to 250 m./sec. Considering the fact that this method gives only the velocity components, which are always higher than the true velocity, it may be seen that these values are in fairly good agreement with the values of 80–160 m./sec. observed by Munro[2] for the actual velocities of travelling disturbances in the F-layer. All the records have shown that the general direction of travel of these disturbances is from Dacca to Calcutta. If we take into account the fact that the directions of travel of these disturbances in the northern and southern hemispheres are opposite, the general southerly movement of these disturbances observed in this investigation is in good agreement with the northerly direction of movement observed by Munro[2] for the months May–June and by Y. V. Somayajulu[1] for the months of June–November.

Simultaneous records obtained on Madras–Mysore and Ceylon–Madras transmissions did not show significant evidence of the presence of these travelling disturbances, probably because these stations have a large separation and are not in a line with the receiving station. The Calcutta–Dacca stations, however, are almost in a line with the receiving site at Waltair and have a comparatively small separation of 240 km. This may be the main reason for the large number of travelling disturbances observed in

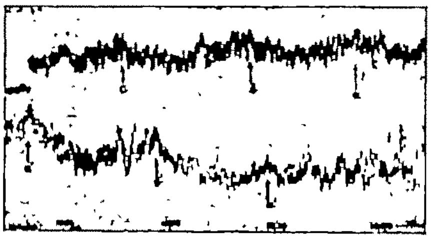

Fig. 1

most of these latter records. In this investigation, although we have ascribed prominent similarities in the records to travelling disturbances, no conclusions can be drawn regarding the nature or type of travelling disturbances in the *F*-layer. Further investigations are in progress with the purpose of extending the usefulness of this method to get full information on the actual wind velocities and directions by simultaneous study of transmissions from three distant transmitters. A full report of these investigations will shortly be published elsewhere.

Quantitative Determination of Ethylene Oxide Products in Aqueous Solutions or Dispersions

In recent years, the use of ethylene oxide condensation products as detergents, wetting agents, finishes, and so on, has steadily increased. This makes an analytical method for the determination of such products more and more desirable. In most cases, it is felt, an accuracy of ± 5 per cent is sufficient. The method must be rapid and simple enough for practical purposes.

For a considerable time it has been known that ferrocyanic acid gives addition products with oxygen-containing organic compounds. Starting from this fact, the possibility of using potassium ferrocyanide for the analytical determination of ethylene oxide condensation products was examined. After several modifications the following method was devised.

To a certain volume of the aqueous solution or dispersion of the ethylene oxide product, hydrochloric acid is added while stirring. Then a known quantity (A) of potassium ferrocyanide is added.

The flaky precipitate is filtered and the remaining potassium ferrocyanide in the filtrate (B) is estimated by titration with zinc sulphate. $A - B$ is the quantity of potassium ferrocyanide consumed by the formation of the precipitate.

For each ethylene oxide condensation product a fixed relation exists between the quantity of potassium ferrocyanide necessary to precipitate a certain amount of ethylene oxide condensation product. This relation (f) can easily be determined using a known quantity of ethylene oxide product. For a solution or dispersion containing an unknown quantity of the same ethylene oxide condensation product (x) it then follows that:

$$x = f\ (A - B).$$

Determinations have been carried out on nonyl phenol condensed with 6, 9 and 12 moles of ethylene oxide in varying dilutions between 0·15–3 gm. per litre. Results obtained show that the value of f for each adduct in the interval 0·6–3 gm. per litre is a constant generally within ± 5 per cent.

A relationship seems to exist between the number of moles of ethylene oxide present in one mole of condensation product and the number of moles of $K_4Fe(CN)_6$ required for precipitation. Thus, in th above-mentioned interval, approximately 0·7, 1·0 an 1·5 moles respectively of $K_4Fe(CN)_6$ were necessar for the precipitation of one mole of nonyl phen condensed with 6, 9 and 12 moles respectively ethylene oxide.

Investigations on this subject, especially wit regard to its scope, are being continued, and a detaile description of the method, together with result obtained, will be published at a later date.

The interest of Mr. H. Grunewald and the helpfu assistance of Miss Birgitta Andersson and Mi Marianne Dahlström in carrying out the experiment are acknowledged.

A New Synthesis of Carbazoles

It has been observed that upon attempted di tillation of the oxime of 2-phenylcyclohept-2-enon in a high vacuum, thermal cyclization takes plac with the formation of cycloheptenoindole[1]. If th generality of this reaction could be demonstrated, valuable new route would be available toward obtaining certain natural products containing th indole nucleus, employing starting materials mor readily available than those containing a preforme indole system. We wish to report the extension the thermal cyclization reaction of oximes to a numbe of new cases.

Thermal cyclization of the oxime of 2-phenylcycl hexanone yielded 1,2,3,4-tetrahydrocarbazole, m.p 124–125° (from aqueous ethanol). Admixture wit an authentic sample prepared from cyclohexanon phenylhydrazone showed no melting point depressio The infra-red spectra of both specimens were identica

Similar treatment of the oxime of 2-phenylcyclo hex-2-enone yielded carbazole, m.p. and mixed m. upon admixture with an authentic specimen, 242 The infra-red spectra of both specimens were identica

Thermal treatment of the oxime of 2-(2′,3 dimethoxyphenyl)cyclohex-2-enone yielded 1,2-d methoxycarbazole, m.p. 134° (from ethanol). (Ana calc. for $C_{14}H_{13}O_2N$: C, 74·0; H, 5·8; OCH_3, 27· per cent. Found: C, 73·7; H, 6·0; OCH_3, 27·6 pe cent.)

Similar treatment of the oxime of 2-(2′,3′-dimeth oxyphenol)cyclohexanone yielded 1,2,3,4-tetrahydr 5,6-dimethoxycarbazole as a viscous oil, b.p. 180 (2 mm.). (Anal. calc. for $C_{14}H_{17}O_2N$: OCH_3, 26·8 pe cent. Found: OCH_3, 27·1 per cent.) Treatment the oil with palladium–charcoal in boiling cymen gave 1,2-dimethoxycarbazole identical with th product obtained above.

This novel cyclization reaction appears to involv the direct attack of the oxime nitrogen atom on a aromatic nucleus. The reaction is being extended t other systems, and its mechanism is being investigate

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 2

British Occupational Hygiene Society (at the London School Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), 11 a.m.—First Conference.

Society of Engineers (at the Geological Society, Burlington use, Piccadilly, London, W.1), at 5.30 p.m.—Mr. A. J. Harris: restressed Concrete in Civil Engineering Works".

Society of Chemical Industry, London Section and Food oup (in the Chemical Society's Rooms, Burlington House, Picca- ly, London, W.1), at 6.30 p.m.—Mr. A. G. Ward: "Recent Advances Gelatin Research".

Tuesday, November 3

Arthur Stanley Eddington Memorial Trust (at the Arts' hool, Bene't Street, Cambridge), at 5.30 p.m.—Prof. H. H. Price . ome Aspects of the Conflict between Science and Religion" (Edding- n Lecture).

Institution of Electrical Engineers, Measurements Section . Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Stand- lized Protective Transformers from the Point of View of Maker and er".

Royal Institution (at 21 Albemarle Street, London, W.1), at p.m.—Mr. N. Tinbergen: "Social Life of Animals". (Further ctures on November 10, 17 and 24.)

Tuesday, November 3—Thursday, November 5

Ministry of Agriculture and Fisheries (in conjunction with the ricultural Research Council, the National Farmers' Union, e British Agricultural Contractors Association, and the sociation of British Insecticide Manufacturers, at the St. orge's and Norfolk Hotels, Cliftonville, Margate)—National Weed ntrol Conference.

Wednesday, November 4

Physical Society, Colour Group (in the Lecture Theatre, stitute of Ophthalmology, Judd Street, London, W.C.1), at 3.30 p.m. Dr. W. A. H. Rushton, F.R.S.: "Chemical and Nervous Factors Scotopic Dark Adaptation"; Dr. R. A. Weale: "Some Properties the Cat's Eye".

Geological Society of London (at Burlington House, Piccadilly, ndon, W.1), at 5 p.m.—Scientific Papers.

Presentation of Technical Information Discussion Group n the Anatomy Theatre, University College, Gower Street, London, .C.1), at 6 p.m.—Mr. M. G. Scroggie. "Problems of Technical uthorship".

Society of Public Analysts and Other Analytical Chemists the Chemical Society, Burlington House, Piccadilly, London, W.1), 7 p.m.—Scientific Papers.

Pharmaceutical Society of Great Britain (at 17 Bloomsbury uare, London, W.C.1), at 7.30 p.m.—Mr. T. C. Denston: "General rvey of the British Pharmacopoeia 1953".

Thursday, November 5

University College, London (in the Anatomy Theatre, Gower reet, London, W.C.1), at 1.15 p.m.—Prof. K. Lonsdale, F.R.S.: rystallography, Ancient and Modern".*

Royal Society (at Burlington House, Piccadilly, London, W.1), 4.30 p.m.—Dr. K. M. Smith, F.R.S.: "Some Aspects of the ehaviour of Certain Viruses in their Hosts and of their Development the Cell" (The Leeuwenhoek Lecture).

Mineralogical Society (at the Geological Society of London, urlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific apers.

Institute of Fuel (at the Institution of Mechanical Engineers, torey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. . Couture: "French Power Resources and their Utilization".*

Institution of Electrical Engineers (at Savoy Place, London, .C.2), at 5.30 p.m.—Mr. J. S. Cliff: "The Co-ordination of Insulation High Voltage Electrical Installations".

Royal Anthropological Institute (at 21 Bedford Square, ondon, W.C.1), at 5.30 p.m.—Dr. Audrey I. Richards: "Agora- hobia in Anthropology".

University of London (at Birkbeck College, Malet Street, London, .C.1), at 5.30 p.m.—Prof. Joseph Doyle (Dublin): "Polyembryony Conifers". (Further Lecture on November 6.)*

Royal Institution (at 21 Albemarle Street, London, W.1), at p.m.—Dr. R. W. G. Hunt: "The Fundamentals of Colour Repro- uction". (Further Lectures on November 12, 19 and 26.)

Institute of Metals, London Local Section (at the Royal chool of Mines, South Kensington, London, S.W.7), at 7 p.m.—rof. F. A. Forward: "The Preparation and Properties of High urity Nickel Powder".

Chemical Society (in the Chemistry Lecture Theatre, Imperial ollege of Science and Technology, London, S.W.7), at 7.30 p.m.—r. A. W. Johnson: "Aromatic Character in Seven-Membered Ring ystems" (Tilden Lecture).

Friday, November 6

Institute of Physics, London and Home Counties Branch at 47 Belgrave Square, London, S.W.1), at 5.30 p.m.—Prof. R. H. eierls, F.R.S.: "Recent Progress on our Knowledge of Fundamental Particles".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. J. H. Schulman: "Molecular Interactions at the Solid/Liquid Interface with Special Reference to Flotation and Solid Stabilized Emulsions".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Deputy Coal Survey Officer (with good honours degree in chemistry, fuel technology or geology, or equivalent qualification, and preferably with industrial experience and experience in laboratory control) at the Coal Survey Laboratory, Sheffield—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/690 (November 7).

Principal and Senior Scientific Officers (with first- or second-class honours degree in mechanical engineering, with metallurgical experience; or first- or second-class honours degree in metallurgy, with engineering experience), at the Atomic Energy Research Establishment, Harwell, for fundamental studies of nuclear reactor design, involving assessment of metallurgical and materials problems relative to engineering design requirements—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting C.529/53A (November 7).

Scientific Officer (B.Sc., with first- or second-class honours, or equivalent qualifications, with chemistry as the principal subject, and capable of undertaking general silicate analysis, and preferably with specialized experience in investigation of clays and cement-making materials) in the Mineral Resources Division of the Colonial Geological Surveys, London—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.318/53A (November 12).

Lecturers (2) (with honours degree in electrical engineering, and industrial experience, and preferably with some teaching experience) in Electrical Engineering—The Secretary of University Court, The University, Glasgow (November 14).

Assistant in Natural History—The Secretary, The University, Aberdeen (November 15).

Chief Engineer of the North Eastern Electricity Board—Chairman of the North Eastern Electricity Board, Carliol House, Newcastle-upon-Tyne 1 (November 16).

Junior Fellowship in Aeronautical Engineering—The Registrar, The University, Bristol 8 (November 18).

Senior Research Officer or Research Officer (Textile Scientist) (preferably with honours degree in textile science, physics, or some branch of engineering, and with several years experience in the textile industry) in the Physics and Engineering Unit, Wool Textile Research Laboratory, Commonwealth Scientific and Industrial Research Organization, Sydney, to develop a programme of research into the physical properties of wool fibres or of fibre assemblies or into the physical principles of textile processes—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 465/34 (November 21).

Senior Lecturer or Lecturer in Chemical Pathology at the University College of the West Indies—The Secretary, Senate Committee on Higher Education in the Colonies, University of London, Senate House, London, W.C.1 (November 23).

Senior Research Officer or Research Officer (with honours degree with chemistry as a major subject, or equivalent qualifications, and experience of research in coal tar chemistry) in the Coal Research Section, Commonwealth Scientific and Industrial Research Organization, Sydney, Australia, to carry out investigations into the chemistry of coal tar and to supervise the examination of the chemical products of coal carbonization—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2 (November 27).

Junior Physical and Organic Chemists (with first- or second-class honours degree in chemistry, and two or three years research experience in physical or organic chemistry) in the Department of Sugar Technology and Chemistry, Imperial College of Tropical Agriculture, British West Indies—The Secretary, Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2 (November 30).

Structural Engineer to investigate new structural techniques and experimental methods, with special regard to multi-storeyed buildings—Architect, (AR/EK/SHH/1), County Hall, London, S.E.1 (November 30).

Lecturer in Biology, and a Demonstrator in Biology (with honours degree with zoology as the principal subject) in the Department of Zoology and Comparative Anatomy—The Dean, The Medical College, St. Bartholomew's Hospital, London, E.C.1 (December 1).

Professor of Physics—The Secretary and Registrar, University College of North Wales, Bangor (December 15).

Chair of Moral Philosophy—The Secretary, The University, St. Andrews (December 31).

Assistant Agricultural Economist (graduate in economics and/or agriculture) at the School of Agriculture, Sutton Bonington—The Registrar, The University, Nottingham.

Assistant Engineers and Assistant Hydrologists (with university degree or diploma in civil engineering and at least two years experience on survey, preferably with River Catchment Boards or Irrigation Schemes) in the Department of Hydrological Survey, Uganda, for duties which will include the erection of river and lake gauging stations, the collection and computation of hydrological data, the survey and design of land drainage and investigation schemes—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.189/9/01.

Assistant Meteorologist (with H.S.C. or equivalent in mathematics and physics, and preferably with practical forecasting experience) with the Trinidad Government—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M3B/33526/NF.

Botanist (Plant Breeder) (with good honours degree in botany, training in plant breeding, and some knowledge of statistics as applied to field experiments, and at least two years postgraduate experience) at Rokpur Rice Research Station, Sierra Leone—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.87/15/01.

CHEMIST to assist in laboratory dealing with members' day-to-day production problems—The Printing, Packaging and Allied Trades Research Association, Randalls Road, Leatherhead, Surrey.

COURTAULDS RESEARCH FELLOWS (2) (with first- or upper second-class honours degree in chemistry) IN THE RESEARCH LABORATORY, Maidenhead, for work of a fundamental nature in physical and/or organic chemistry—The Director of Personnel, Courtaulds, Ltd., 16, St. Martin's-le-Grand, London, E.C.1, quoting Ref. No. D.36.

ENGINEERS and PHYSICISTS, Experimental Officer and Assistant Experimental Officer grades, in Royal Naval Scientific Service Experimental Establishments in the London, Portsmouth, Weymouth and Gloucestershire areas, and Scotland—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.247/53A.

GEOLOGIST (with first- or second-class honours degree in geology, and preferably with more than two years postgraduate experience) in Fiji, to assist the Senior Geologist to map, geologically in detail, mineralized areas in the Colony—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE. 105/49/01.

GRADUATE PHYSICIST of ELECTRICAL ENGINEERING for research and development in connexion with industrial process measuring and control instruments—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "Instruments"

INTERNATIONAL WOOL SECRETARIAT RESEARCH SCHOLAR (with qualifications in physical chemistry) for work on research on the structure of the wool fibre—The Principal, Technical College, Bradford 7.

MICROBIOLOGIST or BIOCHEMIST (with diploma in bacteriology and/or first- or second-class honours degree in biochemistry, and with some microbiological experience) for research on rumen fermentation mechanisms—The Secretary, Rowett Research Institute, Bucksburn, Aberdeenshire.

PASTURE RESEARCH OFFICER (with university degree in agriculture or botany and preferably with some experience in grassland work) in the Sudan Veterinary Service, for duties which will include preliminary experimental work and supervision of grazing developments and improvement—The Sudan Agent in London, Sudan House, Cleveland Row, St. James's, London, S.W.1, quoting "Pasture Research Officer 2201".

PRINCIPAL SCIENTIFIC OFFICER (geophysicist) (with good honours degree in physics or geology, and several years practical experience of seismic and gravitational prospecting and general knowledge of other methods of geophysical prospecting) for duties initially at London headquarters, Directorate of Colonial Geological Surveys, and later considerable periods in Colonial territories, Ref. A.204/53A; Two SENIOR SCIENTIFIC or SCIENTIFIC OFFICERS (Geologists) (with good honours degree in geology, and experience in field mapping, preferably in Colonial or similar territories) for duties in the Photogeological Section, Directorate of Colonial Geological Surveys, Tolworth, Surrey, Ref. G.273/53A—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

PROFESSOR OF AGRONOMY at the Iraq Agricultural College, Baghdad—Royal Iraqi Embassy, 22 Queen's Gate, London, S.W.7.

RESEARCH ASSISTANT (with honours degree in physics, and preferably with experience in vacuum physics) IN THE PHYSICS DEPARTMENT—The Professor of Physics, Physics Research Laboratories, 78 Upper Redlands Road, Reading.

Osram

FOR USE IN
EQUIPMENT
SUBJECT TO
CONDITIONS OF
VIBRATION
AND
SHOCK

Q VALVES

The Osram 'Q' series of Special Service Industrial Valves have been specially designed to give improved performance under abnormal conditions of vibration and shock. For example in Aircraft Radio systems, Marine communications, Mobile equipment, Industrial plant control, etc. Their design is based on the field performance of a number of the most popular Osram types, but many additional operations have been added to the standard process of manufacture. These features allied to strict statistical quality control at all stages of manufacture ensure a high order of dependability under onerous operating conditions so vital in equipment that can be completely shut down as the result of the failure of a single component.

INITIAL LIST OF SPECIAL SERVICE INDUSTRIAL VALVES

TYPE No.		ELECTRICAL CHARACTERISTICS AS			LIST PRICE
		OSRAM TYPE No	R.T.M.A. No.	SERVICES No.	
QA 2400	Miniature vari-mu R.F. pentode.	W77	—	CV 131	19 6
QA 2401	Miniature triode.	L77	6C4	CV 133	15 0
QA 2402	Miniature output pentode.	N77	6AM5	CV 136	19 6
QA 2403	Miniature R F pentode (high slope, sharp cut-off).	Z77	6AM6	CV 138	1 6 3
QA 2404	Miniature double diode.	D77	6AL5	CV 140	13 6
QA 2405	Transmitting double tetrode.	TT15	—	CV 415	6 7 6
QA 2406	Miniature double triode.	B309	12AT7	CV 455	1 6 3
QA 2407	Miniature full wave rectifier.	U78	6X4	CV 493	15 9
QA 2408	Double triode, octal base.	B65	6SN7GT	CV 1988	1 6 3

Full data and Information on the Osram 'Q' Special Service Industrial Valves is contained in leaflet OV2022. Write for a copy today to the Osram Valve and Electronics Dept.

FLOOD CONTROL AND WATER CONSERVATION

THE leading article in *Nature* of August 15, p. 263, directed attention to the fact that, although the floods along the east coast of Britain and the London fog disaster had both produced official committees of inquiry to investigate and report upon the problems of tidal flooding and smoke pollution, no similar action followed the Lynmouth disaster in relation to the more frequent problem of river flooding. Correspondents ranging over a wide field of interests have raised numerous points in support of the committee of inquiry which the article advocated, and a reassessment of the problem is now made in the light of the communications received.

The first statement drew a distinction between periodic and episodic types of flooding. The periodic type is the fairly regular flooding related to a repetitive régime in the life of the river, conditions which local inhabitants normally expect from year to year. From time to time, however, exceptional circumstances of rainfall or snow-melt produce exceptional inundations, especially in the lower reaches of the larger river basins.

Episodic flooding, on the other hand, is related to abnormally heavy storms, and these although occurring infrequently in any one locality may cause much damage to property and occasion much loss of life as a result. Some notable historic cases were mentioned in the previous article, culminating in the Exmoor disaster of August 15, 1952, which caused twenty-eight deaths, and the loss of much of Lynmouth and seventeen bridges. Episodic flooding does not appear to be generally recognized yet as a frequent natural hazard in the meteorological conditions experienced by the British Isles—the infrequency in any one locality tends to mask the over-all picture. An examination of the records since the Lynmouth disaster will, however, serve to illustrate this point. A general consensus of opinion throughout Britain would probably regard the period which has since elapsed as fairly dry, with no memorable rainfall or flooding. As a fall of between two and three inches of rain in a day is regarded as exceptional and potentially dangerous (especially when falling on already saturated ground), it is interesting to find that the official records so far published reveal some sixty to seventy occasions of such heavy precipitation since the Lynmouth disaster. Of the local flooding caused by these occurrences, the most notable subsequent to the North Devon and North Somerset floods of August 15–16, 1952, included the serious flooding in Sussex on November 27, 1952; and that of May 24–25, 1953, in northern England and south-west Scotland, when there was much damage to roads and bridges, and some loss of life. The heavy June storms noted above were also responsible for severe flooding and considerable damage, several bridges being swept away in the Lake District. More recently, there has been loss of life, much damage and two bridges swept away in floods in the Afan Valley of Glamorganshire (August 20), while a bridge in the Troutbeck Valley of the Lake District, rebuilt after the June floods.

was demolished for a second time on August 31. Heavy falls of rain at the end of September again resulted in flooding in Langdale, and bridges were lost in the Lochaber district of Inverness-shire. November 1 saw heavy rainfall in southern England.

The picture revealed for the past year is repeated again and again in the past, and will clearly recur in the future. The records in "British Rainfall" reveal falls of from two to three inches of rain a day as a common occurrence, while four inches or more in one day can be expected at least once in every year somewhere in Britain, and a fall of six inches or more in one day occurs at least once somewhere in Britain in five years out of ten. It is true, of course, that many of these heavy rainfalls take place in normally wet districts; but no part of the country, on the basis of the available meteorological evidence, is completely immune from storms of potentially dangerous duration and intensity. Even in the wetter districts these heavy falls can be quite disastrous (for example, Rhondda Valley, November 11, 1929, Tweed Valley, August 12, 1948, and Exmoor, August 15, 1952). With our present meteorological and geomorphological knowledge, however, it would not be difficult to define and map those areas most susceptible to exceptional precipitation of the episodic type, and to demarcate those localities where damage is most likely to occur.

The possibility of flood control through various precautionary measures, including check dams and reafforestation, together with care in agricultural and industrial utilization of the land, is of course intimately linked to the wider problem of water conservation. Correspondents have been quick to point out that increasing demands are being made upon the water resources of Britain and that serious problems already exist in some areas. Hitherto regarded as an almost inexhaustible raw material, lack of water is now beginning to limit certain industrial undertakings. Electric power stations dependent on coal for energy need vast amounts of water for condenser units. An increasing population and a rising standard of living involve an increasing consumption of water. In the Midlands and east and south-east England, the demand now nearly equals the available supply from surface and underground sources.

Looking farther ahead, the possibility on a large scale in Britain of the controlled growth of crops and grass by summer irrigation (already demonstrated by successful experiments at Rothamsted Experimental Station) may produce further exceptional demands for water. The amount needed by the land to obtain maximum cropping can now be calculated with reasonable accuracy, and for a dry summer in south-east England almost astronomical figures emerge—up to 250,000 gallons per acre could be usefully applied. The possibility of large demands on water supplies by atomic energy and power stations must also be taken into consideration. All these trends may in time completely alter our conventional attitude towards water, and the conservation of much more, if not all, of our supplies may become imperative. Flood control need not therefore be regarded as a wholly negative, non-productive precautionary measure to avoid loss of life and structural damage to roads, railways and bridges, but as a vital link in the conservation of one of our most valuable assets.

Actions and decisions, however, need to be based upon sound and accurate information. We have adequate rainfall data from the Meteorological Office, details of underground water supplies are known to the Geological Survey, and reasonable historical records of exceptional floods also exist. But there is a regrettable deficiency in hydrological data, which has been accentuated by the unfortunate suspension of the Inland Water Survey in June 1952 on the grounds of economy. The Survey had the responsibility of initiating the development of a systematic and comprehensive network of surface-water gauging stations, together with the publication of hydrometric data: it was started very largely as a result of pre-war representations to the Government by the British Association for the Advancement of Science and the Institution of Civil Engineers, and it became one of the responsibilities of the Ministry of Housing and Local Government. The suspension of the Survey was a strange *non sequitur* after the passing of the River Boards Act in 1948 and the adoption of the following resolution in August 1951 by the International Union of Geodesy and Geophysics: "The U.G.G.I., considering that a great many hydrological data are lost because in many countries there exists no central hydrological organization, recommends that the national committees in such countries should encourage their governments or other appropriate agencies to inaugurate such an organization or coordinating body".

Correspondents from both academic and engineering circles have directed attention to the lack of hydrological data—an essential link in the chain of information. Others have suggested the need for strengthening the river boards, which in some areas appear to exist in name only. The need of planning authorities for more detailed information, the desirability of broadening the knowledge of the civil engineer and providing a code of practice, and the question of flood-warning systems in dangerous areas have also been raised. The present wide dispersal of responsibility in Government circles and the lack of any policy with respect to flood control and water conservation (especially as revealed by the suspension of the Inland Water Survey) have also brought forth comment.

Some pre-war pioneer work of investigation already exists in the valuable report of a committee of the Institution of Civil Engineers, on floods in relation to reservoir practice. This committee was set up as a result of the passing of the Reservoirs (Safety Provisions) Act 1930, and it published an interim report in 1933. The time now seems opportune for a re-examination of the problem, and the now wider ramifications inevitably suggest the desirability of instituting a widely representative committee of inquiry to ascertain existing responsibilities and their limitations, to make such recommendations for immediate action as appear desirable, and to provide guidance for future policies with respect to flood control and water conservation.

SELECTION OF SIR HENRY DALE'S PAPERS

Adventures in Physiology

With Excursions into Autopharmacology. A Selection from the Scientific Publications of Sir Henry Hallett Dale. With an Introduction and Recent Comments by the Author. Pp. xvi+652. (London: Pergamon Press, Ltd., 1953.) £6 6s.

HISTAMINE, acetylcholine and noradrenaline are powerful drugs and naturally present in the body; discussions about them occupy a large proportion of the available time at meetings of the Physiological Society and the British Pharmacological Society. Drugs which oppose them or release them, enzymes which form them or destroy them and drugs which oppose the enzymes, can all be regarded as part of the subject of autopharmacology, which has provided the pharmacologists with a topic of general fundamental importance. Sir Henry Dale is both the father and the godfather of this subject. He was the first to recognize the importance of all these three substances and to make detailed studies of their actions, and he provided the subject with a name which is still less widely used than it might be.

A selection of thirty of Sir Henry's most important papers has now been published in a fine book with an introduction and recent comments on each paper by the author. The selection has been confined to those papers at the head of which Sir Henry's own name appears, and this limitation has led to the exclusion of papers from his laboratory to which he made important contributions without taking credit for them. There is, however, no lack of material, as is shown by the bibliography of 253 items included at the end of the book. The selected papers are those which have told exciting new chapters in two stories, the story of the chemical transmission of impulses at nerve endings and the story of the physiological function of histamine. Here are many famous tracings on smoked paper which are familiar in the text-books although their original source is not always realized. Here are new ideas, now generally accepted, put forward with the explicit clarity which made them immediately convincing. Here is an introduction which tells us how in 1904 Dr. Henry Dale at the age of twenty-nine decided to accept a research post under Mr. (later Sir) Henry Wellcome, and of how so many other men who were later to become famous joined him there, and of the accidents which they turned into great opportunities. Mr. Wellcome said that he wanted work of permanent value to science to be done in his laboratories, but that he would also be grateful if the study of ergot could be rescued from the morass into which it had fallen. Both these wishes were triumphantly fulfilled when the study of ergot provided the inspiration for so many fundamental physiological discoveries.

"Adventures in Physiology" contains penetrating comments on each paper, which turn an anthology into a connected story, filling in gaps, adding human interest, and showing how the tale has unfolded in more recent years. These comments show that the author's brain is still more active than most other people's brains, and that he can still help to clear the thoughts of those who seek to follow in his footsteps. He has little to regret except that he did not always succeed in foreseeing what no one else foresaw; the few mistakes he has made have been turned to good advantage and provided clues for new advances.

The book is well produced and will be preserved in all medical libraries as a model of the way in which scientific discoveries should be made, and of the way in which scientific papers should be written.

J. H. GADDUM

THE OUTPUT OF A UNIVERSITY

Alumni Cantabrigienses

A Biographical List of all known Students, Graduates and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. Compiled by Dr. J. A. Venn. Part 2: From 1752 to 1900. Vol. 5: Pace–Spyers. Pp. iv+614. (Cambridge: At the University Press, 1953.) £10 10s. net.

THE first volume of "Alumni Cantabrigienses" appeared in 1922. The monumental task undertaken by the late Dr. John Venn and his son, Dr. J. A. Venn, now president of Queens' College, Cambridge, is drawing near completion. Of the six volumes allotted by Dr. Venn to Part 2, for which he has been alone responsible, only one further volume now remains to be published.

The present volume naturally repeats the main features of the previous volumes of Part 2: the great preponderance of clerics among the University graduates of the years 1750–1900 remains very marked. Many clergymen had distinguished careers, like George Augustus Selwyn, first Bishop of New Zealand, in memory of whom Selwyn College was founded. Others like Stanley P. Smith, one of the famous "Cambridge Seven", Charles Simeon, leader of an Evangelical group, and William Paley, of the "Evidences of Christianity", are remembered for different reasons. Curious side-lights are given on the lives and views of others: H. T. Robins, being suspicious of the wine he was preparing for communion, saved the lives of one or more of his congregation, but lost his own, by tasting it: it proved to be caustic soda.

Of the many distinguished scholars, only a few can be mentioned: W. Robertson Smith, a member of the Old Testament Revision Committee in 1875, E. H. Palmer, professor of Arabic, murdered by Arabs when on a secret mission in Egypt, Adam Sedgwick and William Ridgeway were all colourful personalities, as also was Richard Porson, who was regius professor of Greek for sixteen years but never resided in Cambridge during the tenure of his chair. Of a different type was S. G. Phear, Master of Emmanuel College, who retired from the mastership after twenty-four years of office—an action described by another and older head of a college as "a most immoral proceeding". Of schoolmasters, the names of Sanderson of Oundle and T. E. Page of Charterhouse stand out; Samuel Parr, who "flogged after the old fashion", H. S. S. Salt of Eton, who renounced flesh food, declaring his colleagues to be "but cannibals in cap and gown", and J. P. Plumptre, also of Eton, who stigmatized Catholic emancipation as "the wickedest thing since the Crucifixion", are mentioned here as typifying a different class of schoolmaster.

Politicians play a prominent part in the list of biographies. It may suffice here to mention three Prime Ministers of Britain—Pitt, Lord Palmerston and Perceval, who was assassinated in the lobby of the House of Commons—and two Commonwealth Premiers—Smuts and W. P. Schreiner. Another name not forgotten is that of Charles Stewart Parnell. Many soldiers, both regular officers and, during the First World War, temporary officers, passed through the University: Colonel J. V. Scarlett led the charge of the heavy cavalry at Balaclava, routing two thousand of the enemy with his three hundred men; Major-General H. H. Rose did good service in the Indian Mutiny, and later was commander-in-chief in India and became a field-marshal. The Royal Navy is represented by Rear-Admiral H. R. Popham (who survived a court-martial and severe reprimand to become in due course a commander-in-chief) and by a number of naval chaplains; among these was Alexander Scott, chaplain to the *Victory* at Trafalgar.

Writers and journalists include Max Pemberton, Owen Seaman of *Punch* fame, and J. R. Scott of the *Manchester Guardian*. Up to 1900 commerce and industry drew on far fewer members of the University than during the past fifty years, when H. A. Roberts had organized the University Appointments Board. But, if we may judge from some hundred and twenty Fellows of the Royal Society in the list, the desire to improve natural knowledge did attract a number of students to the study of the sciences. The Fellows may be divided into three groups nearly equal in number—those elected on account of a distinguished career outside the range of the natural sciences and those belonging to the A and B sides of science. Members of the first group come mainly from the earlier years covered by the volume. The names of Rutherford and Sherrington, both presidents of the Society, stand out from the main body of the Fellows. Others who may be mentioned include George Paget, who introduced clinical examinations for medical degrees and was one of many distinguished physicians; also Hugh Percy, Duke of Northumberland, who presented to the University Observatory in 1835 the Northumberland telescope and dome, and L. W. (later Lord) Rothschild, who bequeathed his magnificent natural history collection to the British Museum. Finally, among the Fellows of the Royal Society brief mention must be made of the Hon. Charles Parsons, of turbine fame, and, by way of contrast, the Hon. F. J. Robinson (later Viscount Goderich and then Earl of Ripon), the "weakest Prime Minister who ever held office in this country".

It is evident from the long list of Fellows of the Society of Antiquaries how much knowledge of local antiquities throughout the country has been gained owing to their activities. Two accounts of individuals have caught the eye: R. N. Philipps is said to have originated the use in Cambridge of the light blue colours, and W. Purkis was remembered as "Mr. Union" because, as Bishop Watson complained, when the dinner hour was changed in 1762 from 12 to 3, "foolish dons, like William Purkis of Magdalene, talked of combining the scholar and the gentleman".

The world of sport must not be left out of account. E. Provis was winning cups in croquet tournaments in his ninetieth year; C. Powlett was on a committee revising the laws of cricket in 1774; of cricketers, Prince Ranjitsinhji must be named, and, of rowing men, F. I. Pitman. Other types of racing are represented by the Hon. C. S. Rolls, pioneer racing motorist and aeronaut, and by Sir J. Shelley, twice winner of the Derby. G. A. F. P. S. Smyth fought in the last duel in England, while the Marquess of Queensberry, of the 'Queensberry rules', represents boxing; C. Smyth made the first guideless ascent of Mont Blanc, and Benjamin Smith, the first Dissenter admitted to the degree of B.A., made important pioneer voyages in Arctic regions. Joseph Page left the Army to run a cattle ranch in Texas; he suggests to us John Penn, the last proprietor and hereditary governor of Pennsylvania, and L. Shadwell, the last vice-chancellor of England and president of the Society of Psychrolutes. F. J. M. STRATTON

AGRICULTURAL SANITATION IN ASIA

Health and Agriculture in China

A Fundamental Approach to some of the Problems of World Hunger. By James Cameron Scott. Pp. 279. (London: Faber and Faber, Ltd., 1952.) 25s. net.

EVEN those who are interested in the problems of the technologically backward or non-industrialized parts of the world, and those who are well informed on many aspects of these problems, tend to neglect the importance of agricultural sanitation. The significance of this for all populations living under conditions of traditional hygiene is great, but nowhere more so than in the Chinese culture-area, where for many centuries it has been customary to make use of human excreta as fertilizer for crops. As many observers have pointed out, this is an excellent practice from the point of view of agricultural chemistry, since it avoids the waste of plant nutrients and valuable soil constituents which goes on in modern civilization. Perhaps the high levels of Chinese populations would have been impossible without it. But it has also been evident, since the rise of modern medicine, that from the point of view of health it is a major hazard. For centuries China has been a flourishing area for a great many diseases, and it has been calculated that 40 per cent of this was fæces-borne.

In the present valuable book, by a Scottish soil scientist who went to China in 1936 under Baptist missionary auspices, detailed accounts are given of the investigations of a renowned team of scientific students who worked under the leadership of the American parasitologist, Dr. G. F. Winfield, and of whom the author was one. All aspects of the problem were studied and are described here with tables and photographs. The outstanding problem is that of composting excreta with vegetable waste in such a way as to produce a non-pathogenic fertilizing medium. In itself this is not so difficult to solve; but the economic handicap was that over most of the Chinese culture-area there is not sufficient vegetable waste, partly because progressive deforestation has removed alternative sources of fuel. Urgent measures were therefore necessary of re-afforestation with quickly-growing fuel trees, and of rail and road communications which should bring other fuel sources to the villages. The problem will also be eased when greater abundance of chemical fertilizers becomes available.

It appears that the ultimate objective of those who now guide agriculture and health services in China is the abandonment of the age-old system of using human excreta as manure. But this must be a long way in the future, and it is therefore sure that the work of Scott, Winfield and their Chinese collaborators is now finding wide application and close continued study. I was able to see at first hand a year ago the extraordinary progress in public health which has come about during the past few years in China: covered dust-bins in remote villages where no such things had ever before been heard of, mosquito-netting on all windows, cleared drains and oiled swamps, an enormous increase in the production and use of vaccines. This can only have been possible through the full confidence and co-operation of the masses of the ordinary country people—necessary also for putting into practice the lessons which resulted from the work of the Chilu-Yenching group to which the author belonged. How good it would be if he could visit China again (as I feel sure he would wish), to see and advise on these applications in practice. JOSEPH NEEDHAM

TREE-SPOTTING IN MALAYA

Wayside Trees of Malaya
By E. J. H. Corner. Second edition. Vol. 1: Text. Pp. vii+772. Vol. 2: Plates. Pp. v+228 plates+v. (Singapore: Government Printing Office, 1952.) 2 vols., 25 Malay dollars.

THAT a second edition of "Wayside Trees of Malaya" has been found necessary after a lapse of twelve years—five of them war years when sales must have been very low—is a measure of its popularity. This is not surprising, since if ever there was a book which made easy the path of getting to know the trees, this is it.

The book is divided into two volumes, of which Vol. 1 has four parts. Part 1 contains short discourses on the morphology of the various parts of the trees, shapes of the trees, ant-trees and buttress-trees, phenology, a sketch of the Malayan vegetation, and a valuable list of outstanding trees and where examples of these are to be found.

An elaborate set of keys to the families and some genera, largely based upon vegetative characters, with the subsidiary aid of colour of the latex, and flowers and fruits, makes up Part 2. So far as the reviewer has tested them, these keys are adequate, and demonstrate vividly how far one can proceed on the road to identification without flowering and fruiting characters. These keys look simple; but the knowledge upon which they are based is not picked up in books but is the accumulation of experience gained from many hours spent in the field, often at that time of day when "mad dogs and Englishmen" are the only figures in sight. These keys will sometimes fail, as all keys with a limited objective must fail; but we feel that this will be due to a tree not being a true wayside tree, rather than that the key is at fault.

Part 3 includes the families arranged in alphabetical order. Under each family is a key to the genera, and under each genus a key to the species. These keys are kept as simple as possible consistent with adequacy. The text is liberally sprinkled with fine sketches by the author of those parts of the plant which aid identification. The text itself is no mere collection of botanical data, but more often gives the biological life of the plant, its phenology, its synecology, pollination, folk-lore, and so on. Part 4 is taken up with the indexes.

Vol. 2 consists entirely of 228 half-tone plates, the great majority of which are of outstanding merit. These consist of tree portraits and photographs of leaves and flowers or fruits, or both, and are a valuable aid in identification.

The weight of the two volumes is about 5½ lb., which certainly makes the work difficult to carry about. But presumably, in Malaya every potential buyer possesses a vehicle of some sort, so that perhaps this is not the drawback it would be, for example, in Great Britain.

Dr. Corner and the Government Press, Singapore, are to be congratulated on the production of a really useful book. One would like to know how the Press contrived to produce this well-bound, beautifully printed book of 772 pages and 228 half-tone plates at the extremely reasonable price of just under £3.

N. L. BOR

A TRUANT FROM THE PSYCHOANALYTICAL SCHOOL

The Psychology and Psychotherapy of Otto Rank
An Historical and Comparative Introduction. By Dr. Fay B. Karpf. Pp. xii+129+3 plates. (New York: Philosophical Library, Inc., 1953.) 3 dollars.

THIS book is not only a description of Rank's contribution to psychology, but is also an attempt to place him on the same footing as Jung and Adler with regard to Freud. This is unfortunate, since he remained an adherent of the psychoanalytical school until the age of forty-two, and his early death at fifty-five gave him little time to produce enough original work upon which to base a solid reputation after he broke away. In fact, although the author denies it, Rank is an example of Brill's statement that "Reflecting on the works of the Freudian secessionists, I feel that none of them has contributed anything of real value to mental science since they separated themselves from the master". It is, of course, an exaggeration but has some basis of truth.

Rank was more interested in the cultural aspects of psychoanalysis, and this is reflected in his work—as shown in "The Artist", "The Myth of The Birth of The Hero", etc.—an innovation from the point of view of sociology but not of much use clinically. In fact, it is doubtful whether any of his psychotherapeutic devices are of any value. He claimed to abbreviate treatment by fixing a terminal date for it, but this has not been found successful, and his "Will Therapy" seems aimed at conscious rather than unconscious elements. Dr. Fay B. Karpf does not make the most of the very real contributions to theory which Rank did make and, in discussing the trauma of birth, becomes side-tracked in a discussion on "masculine inferiority" and "womb envy" instead of using it to show how far back analysis may be forced.

This book is not an easy one to read: it is prolix, verbose and often difficult to understand. Such sentences as this one (from p. 75) abound: "Unlike the will concept which Rank took over as an organizing concept from the fields of psychology and philosophy after he became sensitized to the therapeutic manifestations of will phenomena, he arrived at the relationship concept directly from his therapeutic observation and experience and his consequent attempt to reinterpret the psychoanalytic conception of transference in terms of mother-centred dependency". Anyone interested in Rank and willing to labour through the complicated prose will find this book of interest; but it will not be of value to the general reader of psychology. The paper and printing are excellent; there are a good bibliography and a seven-page index. CLIFFORD ALLEN

Theory of Wing Sections

Including a Summary of Airfoil Data. By Ira H. Abbott and Albert E. von Doenhoff. (McGraw-Hill Publications in Aeronautical Science.) Pp. viii + 693. (London: McGraw-Hill Publishing Co., Ltd., 1949.) 127*s.* 6*d.*

THIS is a systematic and comprehensive summary of a great mass of data relating to the properties of a large number of wing-sections designed by the NACA. The book really falls into two parts. The first three hundred pages give a rapid summary of aerodynamic theory, the main emphasis being on incompressible flow and on wings of infinite aspect ratio. There is an introductory account of the effects of viscosity and of the effects of compressibility at subsonic speeds. A valuable chapter is concerned with flaps, slots and other high-lift devices. The remaining four hundred pages present data relating to a large number of NACA aerofoils, in tabular and graphical form. First of all, the tables are given for the geometrical form of the aerofoils concerned, together with the velocity distribution over their surface; then there is the usual information on section lift coefficients and moment coefficients, and on section drag coefficients for various angles of attack. The graphs indicate the Reynolds number at which the observations were made, together with information about the roughness of the surface. All the information in the four appendixes which form the second half of the book relates to low-speed measurements, but some account of wing-section characteristics at subsonic speed is given in Chapter 9.

There is no doubt that this book will form a standard reference book for aeronautical engineers, as it contains within the covers of one volume a great mass of information which can only be found with difficulty elsewhere.

The Dynamical Character of Adsorption

By J. H. de Boer. Pp. xv + 239. (Oxford: Clarendon Press; London: Oxford University Press, 1953.) 30*s.* net.

THE time is passing when it is practicable to bring all aspects of sorption, chemical and physical, into the compass of one or two volumes. Rather the future may bring monographs dealing with special fields. This tendency has already shown itself, for example, in the monograph by the late J. K. Roberts, or in various chapters in the several volumes of "Advances in Catalysis". "The Dynamical Character of Adsorption" continues this tendency, in that it deals in particular with kinetic aspects: evaporation and condensation; surface migration; and possible two-dimensional equations of state and their significance in isotherm formulations. The author writes very clearly and in an interesting manner on monolayer sorption, throughout emphasizing molecular mechanisms and their consequences. As an example, one may refer to Dr. de Boer's demonstration that the five isotherm types in the classification of Brunauer may be obtained without considering anything other than monolayer sorption. As a rule, some of these isotherm types are considered to demonstrate multilayer formation. This result emphasizes that experimental data must increasingly be subjected to analysis in terms of free energy, heat and entropy of sorption as well as in other ways. Dr. de Boer says less on the subjects of multilayer sorption and capillary condensation than he does on monolayer sorption. The book has little to say on the detailed thermodynamics or statistical mechanics of adsorption, nor does it deal with various attempts to treat the complexities of multilayer sorption by modifications of potential theory. The treatment is nevertheless mainly from the point of view of theory, and the exposition is lucid and interesting. One may without reservation recommend Dr. de Boer's book to physical chemists whose special field is surface chemistry, while at the same time one feels it should attract the attention of other chemists as a direct, systematic and not too complex application of the kinetic theory to surfaces. R. M. Barrer

The Physical Chemistry of Surface Films

By Prof. William D. Harkins. Pp. xvi + 413. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1952.) 80*s.* net.

THIS volume is almost exclusively a record of the contributions made to the subject by the author. Of the five chapters by Harkins, three have been expanded from articles which he had previously published in Jerome Alexander's "Colloid Chemistry"; but it is made clear in the introduction that but for the availability of these articles it is unlikely that Harkins could have completed the present book before his death in March 1951.

While the book provides an impressive picture of the many and varied contributions which Harkins made to our knowledge of the behaviour of surface films and deals in an interesting way with both the theoretical and practical aspects of the subject, it is often slightly misleading in that credit is not always given to other workers in the same field. Similarly, a list of some two hundred and seventy publications by Harkins includes roughly one-quarter of that number of papers on subjects other than surface chemistry. This, of course, serves to emphasize the breadth of Harkins's interests; but in the opinion of the reviewer it is a little unfortunate that contributions to other fields, such as nuclear chemistry, are not listed separately or omitted from a book bearing the title "Surface Films".

In spite of these comments, this is a stimulating record and should prove of interest to the worker on problems in surface chemistry. James Bell

Finding Nests

By Bruce Campbell. Pp. 256 + 24 plates. (London and Glasgow: Wm. Collins, Sons and Co., Ltd., 1953.) 12*s.* 6*d.* net.

WITH not only his own notes but those of his father and of the late Arthur Whitaker to draw upon, Bruce Campbell has compiled an excellent book on the breeding habits of British birds, with special reference to discovering their nests. The novice will here find a goodly store of information that should be helpful to him in his field-work, and, what is more, information of complete reliability, whether it concerns the willow warbler in some bushy habitat of the English Midlands or the whimbrel on a Shetland moor. The birds are dealt with species by species, concise remarks being made under the headings of "Distribution", "Season", "Habitat", "Nesting Site", "Nest", "Eggs" and "Methods". The paragraph on "Methods" deals with methods of finding the nest, all based on experience. This volume should make an ideal present for a bird-minded boy, sending him bird-nesting not with intent to take eggs but to try to increase our store of ornithological knowledge.

Frances Pitt

THE FOURTEENTH INTERNATIONAL CONGRESS OF ZOOLOGY

THE fourteenth International Congress of Zoology, held in Copenhagen during August 5–12, was ttended by some eight hundred delegates, members nd associates from forty-eight countries, ranging rom Argentina and Australia to Finland and U.S.S.R., from Japan and Hawaii to Canada and the United States; 104 attended from countries of the British Commonwealth. The Congress, under the atronage of His Majesty King Frederik IX of Denmark, enjoyed the hospitality of the University of Copenhagen, in the halls and lecture rooms of which the numerous meetings took place.

At the opening meeting in the Festival Hall of the University the Congress was addressed by the Minister f Finance, Dr. Thorkil Kristensen, who welcomed the members to Copenhagen on behalf of His Majesty; y the secretary-general of the Permanent Committee f the International Congresses of Zoology, Prof. Louis Fage; and by the president of the Congress and of the Danish Organizing Committee, Prof. R. Sparck. Prof. J. Z. Young then delivered his lecture on "Some Thoughts on Zoological Communication" n which he outlined his views on some aspects of he philosophy of zoology. The afternoon and vening were occupied by a visit to Elsinore and a eception by the Lord Mayor and Corporation of the city of Copenhagen at the Town Hall. The greater part of the following six days was taken up by the meetings of the sixteen sections, and of the International Union of Biological Sciences colloquium on he distribution and origin of the deep-sea bottom fauna, at which more than 250 communications were discussed; there were in addition four general meetings.

A colloquium called by the International Committee on Zoological Nomenclature had been in daily session for the week preceding the Congress; it had discussed a great number of nomenclatorial problems, and prepared resolutions for consideration by the Section of the Congress dealing with Nomenclature. These were discussed further by the Section, and the report and recommendations of the International Committee were presented to the final general session the Congress, at which they were formally adopted. survey of these proceedings follows this article.

It was appropriate that a large number of the ommunications laid before a Congress meeting in a ountry of such ancient maritime associations as Denmark should deal with various aspects of marine iology. A high proportion of papers in nearly all he sections was, as would be expected, based upon xperimental work; and although no spectacular ew discoveries were reported, the general quality the communications was high, and the ensuing scussions were lively and instructive. It is mpossible to mention even the titles of all the many papers presented, and the following remarks report nly some items that particularly interested one elegate.

Prof. Emil Witschi (Iowa) proposed to conclude n agreement among vertebrate embryologists conerning some basic principles that should guide the tandardization of numerical systems of embryoogical stages. This could be accomplished by scribing to the nine great sections or periods of evelopment a varying number of numeral standard tages. He suggested the following system: I, Cleavage (1–6); II, Blastula (7); III, Gastrula (8–11); IV, Primitive Streak (12); V, Neurula (13–16); VI, Tail Bud (17–24); VII, Embryo (25); VIII, Metamorphosis (26–34); IX, Fœtus (35–36). Special investigators will differ in their needs for subdivision of periods, and the desire for greater specialization should be met by letter suffixes. The stages are based mostly on features of external morphology, and preference is given to embryonic over extra-embryonic characters, to axial over lateral organs, and to cranial over caudal conditions of differentiation. The terminally additive nature of evolution within the vertebrates is expressed by the conclusion of embryonic development at progressive stages: 25 in fishes, 30–32 in urodeles, 34 in anurans and 36 in birds and mammals.

Chr. Vibe (Copenhagen), in discussing the zoogeography of Greenland, pointed out that a study of the land fauna shows more and more clearly that it is the remnants of an old fauna which had a more or less circumpolar distribution before the glacial period, but which later on became confined to isolated localities distributed over the boreal and arctic area. The fauna has been able to exist during the glacial period and after because the straits on each side must have been more or less closed, restricting the polar currents, so that the Gulf Stream influenced the climate much more than it does at present.

In a study of the ethology of the roe deer, F. W. Braestrup (Copenhagen) concluded that the social organization of the species, which is much less developed in the red deer, is not due to the organization being patriarchal as claimed by Fraser Darling. Roe deer are not patriarchal, and the reason for the looser social structure is merely that roe deer are mostly inhabitants of thick bush.

C. B. Philip, J. F. Bell and C. L. Larson (Hamilton, U.S.A.) reported observations on peak populations of jack rabbits (*Lepus californicus deserticola*) in Nevada, and on evidence of exposure to infection or parasitic infestations which might influence population trends. Sick and recently dead animals were observed; but no major cause for decimation was discovered, nor has any recent 'crash' in population numbers occurred. Serological evidence showed exposure to Western equine encephalomyelitis, rickettsial spotted fever, brucellosis, and, to a much smaller degree, tularæmia. It is not evident that any of these diseases will be involved in the expected general die-off in the whole area. Hewitt's opinion that the cause of the sudden plague which kills off the rabbits at their greatest abundance is probably of a multiple nature may well prove to be correct.

Prof. A. Vandel (Toulouse) gave an account of the recently established "Laboratoire souterrain" at Moulis (Ariège). Part of the laboratory is actually within the cavern of the Grotto de Moulis, and is fully equipped for biological and physiological research. On the surface another building provides further laboratories, library and living accommodation for workers on all aspects of speleology including *biospéléologie*.

Prof. P. Drach (Paris) described his investigations on the coral reefs of the Red Sea, which he explored by means of a self-contained diving apparatus that allowed depths of 50–70 m. to be reached. The reefs of the Far-San Archipelago are superficially very diverse, but are all remarkable for the extreme steepness of their sides, which descend in a series of almost vertical cliffs separated by narrow platforms. The distribution of organisms on the reefs is dependent upon the turbulence of the water, the intensity of illumination, the depth, and the slope of the sides. The physical conformation of the reefs, and the existence of a submarine cliff 650 m. high, fit Darwin's theory of the formation of coral reefs by subsidence.

In his paper on marine bottom substrata and their fauna, Prof. C. M. Yonge (Glasgow) showed that the major factors influencing the distribution of bottom invertebrates are food and the nature of the substratum. The main problem is the potential food value of the deposits, for detritus contains a hundred times more organic carbon than is contained in the total fauna and flora. Knowledge is urgently required about the nutritive value of detritus, and about the factors controlling its local concentration. Bottom associations cannot be regarded as consisting of interdependant organisms as are the members of associations on land. The carnivores depend upon the presence of the suspension- and deposit-feeders; but members of these are all competing for the same food and so would actually benefit if competitors were absent. In this connexion the paper by Prof. C. ZoBell (La Jolla, California) was of great interest; in it he discussed the occurrence of bacteria in the deep sea and their significance to animal life. It appears probable that they provide the first step in the chain of organic food substances at great depths.

But the communication of greatest general interest on marine biology was the lecture, illustrated by a colour film, given by Dr. Anton Bruun (Copenhagen) on the methods and results of the *Galathea* Expedition, 1950–52. The film showed all phases of the voyage, the object of which was to explore the greatest ocean depths, and it was a remarkable experience for most of the zoologists present to see close-up moving pictures of the extraordinary fishes and invertebrates as they were brought on deck from immense depths fresh and in their natural colours, and in many cases still alive. Many of the more striking specimens collected on the voyage were on exhibition in the University Museum, and the vessel herself was lying in the harbour.

A communication from Prof. C. Hubbs (La Jolla, California) gave news of one of the most interesting of the larger Cetacea, the Pacific grey whale, which had been very nearly exterminated by the early years of this century. It has lately made a great recovery in numbers, and as its migration route passes close inshore off La Jolla, the zoologists of the Scripps Institute have been able to make close observations on its numbers. The observations from land have been supplemented by surveys made over the sea and the lagoons of Lower California from a helicopter, and it has been ascertained that a population of many hundreds of the animals frequents these waters. The paper was illustrated by remarkable photographs of the whales taken at close range from the helicopter.

Other aspects of marine biology were discussed, among many others, in papers by G. P. Wells (London) on "Inherent Rhythms in the Behaviour of Worms", D. L. Ray (Washington) on the "Digestion of Wood by *Limnia lignorum*", and Prof. P.-H. Fischer (Vietnam) on "Gasteropodes Excavateurs de Roches littorales".

These communications are, however, no more than a random sample from the immense variety presented to this most interesting and stimulating Congress—a variety ranging from "Paper Chromatograph Analysis of Taxonomic Relationships in *Drosophila*' "Polarized Light and Arthropod Vision", and t "Perception of Low-frequency Vibrations by *Sem tilus atromaculatus*", to the "Display, Breeding Cycl and Phylogeny of Bower Birds", the "Influence Spermatic Hormones on Spawning and Water Flo in the Oyster", and "Wirkungen der Epiphysectom und der Epiphysolbehandlung bei Fischen".

The Danes are the most hospitable of hosts, an in addition to the scientific sessions they had pr pared a very full programme of excursions, reception dances and other social functions that were great enjoyed and appreciated by the members of t Congress—at the closing banquet a footnote on t menu, in which all the main ingredients of the dish were given their scientific names, warned "*Ho nomina sunt conservanda in spiritu vini*", an echo the deliberations of the International Committee Nomenclature.

At the closing General Session of the Congress a invitation conveyed by Dr. E. Hindle from the Roy Society of London to hold the fifteenth Internation Congress of Zoology in London in 1958 was receive with acclamation, and Dr. G. R. de Beer, director the British Museum (Natural History), was elected be its president. British zoologists will hope that t Government will place funds at the disposal of t organizers of the fifteenth Congress on a scale simil to the support afforded by the Danish Governme to the fourteenth. L. HARRISON MATTHEWS

ZOOLOGICAL NOMENCLATURE

AMENDMENTS TO THE INTERNATIONAL COD OF ZOOLOGICAL NOMENCLATURE

THE fourteenth International Congress of Zoolog Copenhagen, August 1953, carried through t second stage of the important and long overd process of overhauling the International Code Zoological Nomenclature, of which the first sta took place at the thirteenth congress held in Pa in 1948. The work on zoological nomenclature Copenhagen was path-breaking as regards bo procedure and achievements, because the procedu was new and without it the achievement would n have been possible.

The procedure differed from that at any previo Congress in two essential respects: first, ve elaborate measures were taken to provide the Co gress in advance of its meeting with an amp documentation on all the nomenclatorial proble to be considered; second, arrangements were ma for the careful consideration and full discussion this material at a colloquium on zoological nome clature which sat daily at Copenhagen for a we prior to the opening of the Congress. The preparatio for this meeting consisted in the publication the International Trust for Zoological Nomenclatu early in 1952 of a special volume (vol. 7) of t *Bulletin of Zoological Nomenclature* containing a di cussion of the major problems of zoological nome clature which had been remitted by the Paris Congre for further study and for consideration five yea later at Copenhagen. This volume was communicat by the Trust to museum nomenclature committe and leading zoological and palaeontological instit tions and served to secure for the Copenhag

Congress a large and representative range of comment on the difficult problems involved. Later—in 1953—these comments, together with the documentation elating to other items on the Copenhagen agenda, were published by the Trust in two special volumes vols. 8 and 10) of the *Bulletin*. In March of this year he Trust issued invitations both to institutions and organizations concerned with systematic zoology including palæozoology) to appoint representatives o the colloquium. In addition, personal invitations were issued to the members of the International Commission on Zoological Nomenclature and to other pecialists known to be interested in nomenclature. When the colloquium opened on July 29, it numbered more than fifty members drawn in almost equal numbers from the Old World and the New. Sixteen meetings were held by the colloquium before the opening of the Congress, and the full and detailed discussions held made it possible to reach agreement upon recommendations to be submitted on all except one of the seventy items on the agenda. Some of he problems involved were of great complexity and might well have led to sharp disagreement, if it had not been for the general desire of all the members of he colloquium to achieve solutions which were both he best obtainable in the circumstances and in addition commanded the general support of interested zoologists.

A further important and novel feature of the procedure adopted at Copenhagen was the clear ecognition for the first time of the essential difference between the advisory functions of the International Commission on Zoological Nomenclature in the egislative field and the strictly judicial functions of hat body. At Copenhagen—unlike at previous congresses—there was no discussion of individual cases, which it was recognized could be dealt with better by the Commission by means of postal votes. The whole of the time available was thus devoted by the Commission, the Colloquium and the Section on Nomenclature of the Congress to the reform of the code. This procedure possesses the great merit that it recognizes that it is vital that reforms of the code hould command the widest possible support of zoologists generally and that, to secure this end, extensive and representative consultations, followed by full discussion, are essential. The practical value of this procedure is attested by the fact that it made it possible to submit to the Congress a comprehensive eport on the whole range of problems considered.

The first and most important single subject dealt with was how to provide means for ensuring that zoological nomenclature shall be both stable and universally accepted. The attainment of this object was sought by a number of means: (*a*) the addition o the code of a preamble stressing that the foregoing were the objects for which it had been established; (*b*) the introduction of machinery for the disposal of he threat to stability represented by dormant *nomina dubia*; (*c*) the recognition (by a majority vote) of the principle of conservation under which, ubject to certain safeguards, a junior synonym which has been in general use for a considerable period will be protected from being replaced by a senior synonym which is virtually unknown and has carcely ever been used; (*d*) the addition of provisions for restricting and designating type localities or nominal species where those given by the original author were either too vague or incorrect. The second addition to the code of great importance was he introduction of provisions for the recognition, subject to strict safeguards, of neotypes as a category of type specimen in cases where the original type material is lost and definite identification is impossible without detailed examination of the structure of a specimen serving as a unique standard of reference.

Next, the Congress introduced a comprehensive series of rules for the naming of taxa belonging to the family-group of categories in place of the wholly inadequate provisions (Articles 4 and 5) in the present code. At the same time, the Congress introduced provisions for regulating the naming of orders, classes and phyla, the one field in which hitherto the code had possessed no provisions and in which the utmost instability and confusion prevails. Under these provisions, names belonging to these groups, like names for all lower categories, will be defined by the type method. The selection of names for units already established in these categories will be made by committees of specialists in the groups concerned, and an opportunity for comments by specialists will be provided before the names recommended by the committees are finally approved by the International Commission and placed on the "Official Lists" established for this purpose by the Congress. Next, the Congress completely overhauled the provisions (Article 19) relating to the emendation of names, wiping away the ambiguities which in the past have led to much confusion and greatly reducing the area within which emendations will be permissible, niceties of etymology and the like no longer constituting a valid ground for emending a name.

Having thus disposed of the major problems referred to it by the Paris (1948) Congress, the Copenhagen Congress dealt also with the large mass of problems which have been brought forward since the Paris Congress. Of these, the following call for special mention: (1) the withdrawal, subject to safeguards in the interests of current practice, of recognition from names first published in synonymies; (2) the introduction of words designed to ensure that for a specific name published subsequent to December 31, 1930, to acquire availability its author must have attempted to indicate the characters relied upon by him as diagnostic for the unit named; (3) the banning of the distribution of microfilms, microcards and the like as a method of 'publishing' zoological names; (4) the reversal of the Paris decision to substitute the page precedence principle for that of the First Reviser for determining the relative precedence to be assigned to names published in the same book and on the same date; (5) the introduction of provisions to prevent the wanton invalidation of specific names as junior secondary homonyms by unions of genera regarded as unjustified taxonomically by specialists in the groups concerned.

Many of the provisions introduced at Copenhagen are marked by a provision of a novel character designed to enable systematists, wherever possible, to take advantage of the means afforded for ensuring stability without having to submit every case individually to the International Commission. By this method, specialists are required to act on the provisions in question immediately upon the appearance in the *Bulletin of Zoological Nomenclature* of a notification of the publication by an author of a paper in which he has taken advantage of the provision concerned. Within specified periods, such action is open to challenge and, if so challenged, the case is to be referred to the Commission for decision. In other cases, the action taken becomes definitive at the end of the prescribed period and the name concerned is placed on the appropriate "Official List" of valid names or on the appropriate "Official Index" of rejected names. This procedure, while of great convenience to systematists, inevitably throws a greatly increased burden of work upon the secretariat of the International Commission and, through the increase in the amount of material to be published in the *Bulletin of Zoological Nomenclature*, will increase still further the financial difficulties of the International Trust for Zoological Nomenclature, the incorporated body which conducts the business affairs of the (unincorporated) International Commission. So serious, indeed, are the difficulties of the Trust—which possesses no income other than that obtainable from the sale of its publications—that the Right Hon. Walter Elliot, chairman of the Trust, paid a special visit to Copenhagen for the express purpose of warning the zoologists and palæontologists there assembled—and, through them, the great scientific institutions in which they work—that it would be impossible for the Trust to continue to maintain the work of the Commission unless a scheme were to be devised for providing the annual income essential for this purpose.

During the Congress, the colloquium drew up a report setting out in detail the recommendations for the reform of the code which it had adopted in the week preceding the opening of the Congress, and this report was discussed in draft both with the International Commission on Zoological Nomenclature and with the Section on Nomenclature of the Congress. As the result of these discussions, the report of the colloquium was submitted jointly by both these bodies to the Copenhagen Congress, by which it was unanimously adopted at the final *Concilium Plenum*. The report of the colloquium accordingly constitutes the official record of the decisions on nomenclature taken by the Copenhagen Congress, and, as such, will be an indispensable work of reference to all systematists until such time as it is possible, on the basis of the Paris (1948) and Copenhagen (1953) decisions, to prepare and promulgate a revised text of the code. In agreement with the Congress and at its request, the International Trust for Zoological Nomenclature is publishing the report of the colloquium in book form. In order to bring this work within the reach of every zoologist, the Trust is subsidizing this publication to an extent sufficient to enable it to be placed on sale for five shillings (75 U.S. cents); copies will be obtainable from the offices of the Trust (41 Queen's Gate, London, S.W.7). It is expected that publication will take place towards the end of November. FRANCIS HEMMING

CHEMICAL RESEARCH LABORATORY, TEDDINGTON

OPEN DAYS

THE annual open days of the Chemical Research Laboratory, Teddington, were held this year during September 22–25. A feature of the previous year was the new building provided for radiochemical work, and this year another new laboratory was open for inspection. This was a building of prefabricated type but specially fitted for microbiological research. It has a floor space of about 3,000 sq. ft. and contains five research rooms, an instrument room, a small library, a general fermentation laboratory with cold
and warm chambers, and a 'kitchen' for the prepara
tion and sterilization of media and glassware. Th
design is such that the risk of contamination o
cultures is brought to a minimum. The air is filtere
before entry, sliding doors are provided to preven
draughts, and the walls and floors are finished t
allow easy cleaning. This building was occupie
during November 1952.

The main topic of the Microbiology Group is th
fundamental study of the metabolism of sulphate
reducing bacteria. Interesting exhibits related to th
counting of these bacteria, and a demonstration wa
given of the presence of cytochromes detected fo
the first time in anaerobic bacteria. The productio
of sulphide and methane by anaerobic digestion o
sewage sludge supplemented with sulphate wa
demonstrated. Another exhibit illustrated the break
down of aromatic compounds by bacteria isolate
from filter beds in which effluents from chemica
works are rendered innocuous. An important sectio
of the Group is the National Collection of Industri
Bacteria. The primary purpose of the Collection
to supply on request cultures of bacteria require
by industry and research establishments, and som
seven hundred cultures were sent out during 1952 t
organizations all over the world. The Collection no
maintains nearly six hundred strains of bacteri
as well as several antibiotic-producing organism
deposited by the United Nations World Healt
Organization. Research is being carried out on th
effect of freeze-drying on the biochemical characte
istics and viability of the cultures.

Earlier work of the Laboratory's Inorganic Grou
revealed that certain flue dusts provide a concen
trated source of germanium and gallium, and th
dusts are now being used commercially for th
production of these elements. A new extension
the work on the recovery of valuable products fro
wastes or low-grade materials is a search for seleniu
in dusts and sludges arising in the purification of th
sulphur dioxide produced by the burning of pyrit
in the new flash-roaster plants. In most of the dus
the selenium content is small, ranging from 10
100 parts per million; but in one type of sludge th
amount rises to 1–2 per cent, while in another typ
three samples of which were shown during the ope
days, the content varies from 7 to 21 per cent on
dry basis. If these sludges occur in sufficient quantit
they may prove to be a useful source of this in
creasingly important element. In addition to pu
germanium and gallium prepared in the laborator
samples of twenty other metals in a high state
purity were exhibited, the most striking of the
being titanium prepared by the van Arkel proce
These metals form part of the stock held by th
Pure Metals Committee of the Department
Scientific and Industrial Research.

The Inorganic Group is also responsible for micr
chemical and spectrographic analyses required eith
by the Laboratory or other stations of the Depa
ment. The sections concerned are well equipped wi
modern apparatus, and the expert teams are prepar
to give advice on the applications of these instrument

The exhibits in the Radiochemical Group we
largely concerned with separation techniques f
metals and acid radicals, with particular emphasis
chromatography and ion exchange. Of special intere
in chromatography is the development of this proce
to geochemical prospecting by a simple and rap
method for use in the field. Extracts of the mine
samples under study are obtained usually by sim

acid treatment. Portions of the solutions so obtained are then applied to the bottom of a rectangular sheet of adsorbent paper on which a series of vertical slots are cut to form separated strips joined at the top and bottom. The sheet of paper is then rolled into a cylinder and placed upright in a beaker containing a small quantity of solvent and upward diffusion allowed to proceed for 10–15 min. The sheet is then removed, dried and sprayed with test solution when coloured bands of the metals become visible. Comparison with standard stains provides a rough quantitative measure of the metal in the sample. This method has proved successful with copper, cobalt, tin, zinc, uranium, lead, gold and niobium.

Several exhibits demonstrated the application of ion-exchange resins to metal separation, and in two of these experiments, dealing respectively with recovery of gold from cyanide solution and separation of copper and nickel, organic solvents were used for elution of metal from the resin. Equipment shown in this building included apparatus for radioactive measurement, automatic testing of the behaviour of ion-exchange resins on repeated treatment with solutions, continuous recording of concentration of metal in solution by a polarographic technique, and fluorimetric determination of uranium. Apparatus and methods for concentration of metals from minerals and ores were also exhibited.

The work of the Corrosion of Metals Group is concerned with the study of corrosion and its prevention in aqueous solutions, in underground conditions and in the atmosphere. In these researches methods of reproducing the effects of prolonged exposure in a short time are required, and many of the exhibits related to such accelerated tests. These included high- and low-speed rotors, a standardized atmospheric test of a simple type, and a totally enclosed 'weatherometer' in which cycles of spray, light and heat could be applied automatically in predetermined proportions. To the same category belongs the study of the corrosion of boiler tubes. Here the effort is directed to the introduction of conditions so that rapid corrosion occurs, reproducing the effect of prolonged use in service conditions. Once this accelerated test is established, it will be used for the study of inhibitive measures. Apparatus assembled for the corrosion of steels by hot flue gases was exhibited.

Much progress has been made in studies of the inhibition of sulphate-reducing bacteria. Examples of well-preserved iron articles, found in the site of an ancient tannery, led to the discovery of the inhibitive action of tannin and tannic acid; certain metallic salts are also effective, and from some non-aggressive soils a species of *Actinomyces* has been isolated which produces a thermolabile substance that also inhibits the bacteria. Elementary sulphur is often found in the products of bacterial corrosion. It has been found that aqueous suspensions of sulphur exert a rapid attack on steel comparable with that of dilute acid, and it is possible that sulphur may play a more important part in underground corrosion than was hitherto suspected. The specific action of sulphur on iron and steel has been applied to the examination of the completeness of other metallic films on ferrous metal surfaces; it has also been applied to the etching of steel, and several striking examples of this were exhibited.

Other subjects illustrated by exhibits included the removal of films from metal surfaces and their examination by the electron diffraction camera, the study of inhibitive action by radiometric tracer technique, the use of electrical measurements in studying paints on steel in sea water, and the application of inhibitors in temporary protectives and in packaging.

The purification of industrially important organic compounds to the highest attainable standard ($\sim$ 99·9 mol. per cent) and the measurement of the physico-chemical properties of such materials has been a leading theme in the work of the Organic Group for some years. For its effective prosecution this project requires specialized techniques and methods which are outside the scope of many industrial or academic laboratories. Nevertheless, the results which flow from this class of work have wide interest: on one hand, accurate and trustworthy data (melting points, boiling points, densities, refractive indices, solubilities, heats of combustion and ultra-violet and infra-red absorption spectra) are accumulated which are of theoretical and practical use; on the other, standard reference samples can be made available to outside workers needing them for calibration or analytical purposes. Several hundreds of such standards have already been distributed. Many of the exhibits exemplified the techniques which have been applied in various parts of this work. Thus, several kinds of very effective fractional distillation columns were shown, including an example of the spinning-band type. Fractional crystallization at temperatures between – 180° and – 20° C. was also displayed in suitable apparatus. Spectroscopic methods are used, in conjunction with the plotting of freezing-point/time curves, for the estimation of residual impurities, and this crucially important side of the work was fully illustrated by assemblages of equipment, much of which, including a mass spectrometer, has been constructed at the Laboratory. Other apparatus displayed was used in accurate measurements of boiling point, heat of combustion, liquid–vapour equilibria and solubility in water.

In a different field of organic work the Intermediates Section of the Organic Group has applied its chief effort to the preparation of new potentially useful materials by carboxylation procedures and to the preparation of new ion-exchange resins containing phosphonic or arsonic acid groups. Work on the applications of isotopically labelled compounds has also been continued. Many exhibits indicated the extent of success which has attended these lines of work during the past year.

In the High Polymer Group work on semi-permeable membranes, the determination of molecular weight, and ion exchange was shown. A new laboratory maintained at constant temperature has been built which is now being used for osmometry and other physico-chemical measurements, and apparatus on show in this laboratory included precision thermostat baths, a light-scattering photometer, interference refractometer and allied equipment. A range of membranes of graded permeability and suited for use in non-aqueous systems has been produced from polyvinyl alcohol. Using membranes of an appropriate permeability, the molecular weights of simple compounds of known structure may be determined by osmometry. Thus details were shown of the determination of the molecular weights of tristearin, pentaiodobenzene and sucrose octaacetate.

A new type of ion-exchange resin containing chelating groups was exhibited. Resins of this type are of considerable potential importance in certain industrial applications of ion exchange. One exhibit showed a chelating resin being used for reducing the copper content of tap water from 1 p.p.m. to less than 0·05 p.p.m. Other ion-exchange materials shown included a range of resins containing ion-exchange groups at the surface only.

RUMINANT DIGESTION

A DISCUSSION on "Ruminant Digestion" took place on September 8 at a joint session of Section I (Physiology) and Section M (Agriculture) of the British Association, during its meeting in Liverpool.

The opening speaker, Mr. A. G. Singleton (University of Liverpool), discussed the significance of the rate of passage of food through the ruminant stomach, and some of the factors controlling it. The efficiency of the ruminant as a cellulose digester depends mainly on the delaying power of the rumen, which determines the time available for cellulose digestion to occur. If the contents of the four stomach compartments are examined in an animal killed soon after feeding, the rumen and reticulum are found to contain pieces of hay or other food of a relatively large size, the omasum always contains very finely divided particles in a relatively dry state, and the abomasum contains particles of about the same size suspended in a more fluid medium. It seems either that particles do not leave the rumen and reticulum until they have attained a certain smallness of size, or that the omasum reduces their size by a grinding action. Rumination and bacterial action tend to reduce particle size in the rumen. There is little evidence of any triturating activity of the omasum; the dryness of its contents could be due to a squeezing action, but it seems more likely that it is produced by water absorption. There is some evidence that the reticulo-omasal orifice has a valve-like action, and the omasum may control the flow of contents from the reticulum to the abomasum.

The feeding of hay or of straw which has been chopped or ground reduces its digestibility, a fact which was assumed to be due to an increase in the rate of passage of the feed. Balch (1950)[1], however, found that when ground hay was fed with normal hay it passed through the rumen more rapidly; but when the whole ration was ground, it remained in the rumen for an abnormally long period, and fibre was less completely digested. The reason for this is unknown, but the shorter time spent in ruminating, which is known to occur when the ration is ground, may be a contributing factor. This would reduce the amount of salivation, and it is known that an increase in the dry-matter/water ratio reduces the rate of cellulose breakdown.

It has been shown that the composition of duodenal contents influences the motility of rumen, reticulum and abomasum. Acid, protein and fat introduced into the duodenum inhibit the movements of these three compartments. Distension of the duodenum and abomasum also inhibits the movements of other compartments. It appears that chemical and physical factors may exert an important influence on the emptying of the stomach, in addition to the factor of particle size.

Mr. Singleton then described an electromagnetic method which is being used for continuously recording flow through the duodenum, and with which the factors affecting the emptying of the stomach are being investigated.

Dr. R. S. Comline (University of Cambridge) spoke on the nervous control of the ruminant stomachs. A strip of reticulum, attached to its blood and nerve supply, contracts in response to stimulation of vagus, right splanchnic nerve (with the right adrenal removed), left thoracic sympathetic chain, and the intravenous injection of adrenaline. The vagal effects are stronger than the sympathetic and are abolished by atropine. The sympathetic effects are unaffected by atropine, but are prevented by sympatholytic drugs, such as 933 *F*., and by vagal stimulation. In chronic experiments, ruminants are unable to survive double vagotomy, which abolishes the normal propulsive motility, whereas the sectioning of both splanchnic nerves is without obvious effect.

In decerebrate calves and lambs, the œsophageal groove closes in response to water flowing over the pharynx, or to stimulation of the cut superior laryngeal nerve, which could also produce reflex swallowing. The reflexes of groove-closure and swallowing are closely integrated, but the two responses are affected differently by different stimuli. Reflex groove contractions can be inhibited by stimulation of the abomasal branch of the vagus. In decerebrate adult animals, reflex contractions of the reticulum could be invoked by stimulating the central ends of the abomasal, reticulo-omasal and reticular branches of the ventral vagus. Stimulation of the hypothalamus can produce movements in the alimentary canal, and even rumination.

Dr. Comline then criticized the tendency to call a particular part of the ruminant stomach a pacemaker. The stomach movements are not myogenic, as are those of the heart; they disappear when all extrinsic nerves are cut. A more profitable analogy, he said, is with the control of respiration, where a central rhythm is modified by afferent stimuli.

Dr. A. T. Philipson (Rowett Research Institute) contributed a paper on absorption from the rumen of the sheep. The rumen, reticulum and omasum are lined by stratified squamous epithelium, but the layer of keratinized cells is much thinner than in skin. The finding that the concentration of short-chain fatty acids is about 7–10 times greater in the rumen than in the abomasum suggests that absorption takes place, and this has been proved by showing the presence of fatty acids in significant concentrations in the blood leaving the rumen. Many investigations have been made on the rates of absorption of short-chain fatty acids, and it is agreed that absorption is more rapid when the *p*H is acidic than when it is neutral or just over *p*H 7, and that an acidic *p*H has a greater effect with propionic than acetic acid, and with *n*-butyric than propionic acid.

A comparison of the fatty acids in the rumen with those in blood leaving the rumen does not agree with these findings. It is found that the proportions of fatty acids in blood and rumen are similar, except that less butyric acid is present in blood. This led to an investigation of the metabolism of these acids by the rumen wall, which showed that considerable losses of butyrate occur, while losses of acetate are small. Metabolism of propionate is increased by the presence of carbon dioxide. The discrepancy is explained by the fact that about half the butyrate absorbed enters the blood stream, the rest being metabolized, while a little less than one-third of the propionate disappears. The acetate losses are likely to be less than 5 per cent of the total. It is probable that the rates of absorption of these acids are related to their metabolism by the epithelium, but the evidence is meagre. Fluoroacetate inhibits their absorption, but not differentially; monoiodoacetate has no effect on the rates of absorption. Phosphorylating mechanisms, therefore, do not seem to be concerned.

With acetate it is possible to study absorption from very weak solutions, as it is not metabolized to any great extent. It is found that absorption is proportionally more efficient for lower than for higher concentrations. A possible explanation is that a mechanism exists for transporting acetate across the epithelium, but as the concentration in rumen rises the mechanism becomes saturated and any further transport is by the slower process of physical diffusion.

Pennington has shown that rumen epithelium *in vitro* can form ketone bodies from butyrate. The oxygen consumption of the epithelium is considerable, even when no fatty acids are present in the medium. Glucose and butyrate increase oxygen consumption, but acetate does not. Propionate increases oxygen consumption only when carbon dioxide is present. Fixation of carbon dioxide occurs during the metabolism of propionate, and at least part of the propionate disappears via the tricarboxylic cycle, for succinate, an intermediary, increases when the cycle is arrested by the presence of malonate. The epithelium shares the unusual ability to form ketone bodies with liver and kidney. Another product of microbial activity is ammonia, and this is absorbed in substantial quantities, 0·3–0·4 gm. ammonia–nitrogen/hr. from concentrations of 50 mgm. ammonia–nitrogen/100 ml.

The removal of end-products is necessary if a reasonably constant environment is to be maintained for the bacteria, and in this respect hydrogen-ion concentration is important. Saliva provides a buffer; but the permeability of the rumen to ions in solution is also important. Any solution in the rumen tends to change to a *p*H of 7·2–7·4, whether acid or alkaline originally, and this is due to a differential passage of ions across the epithelium in both directions. When fatty-acid anions are absorbed, a proportionate amount of bicarbonate enters the rumen In the rumen liquor of normal sheep potassium and inorganic phosphorus are in a much higher concentration than in plasma; magnesium and calcium are also in excess, while sodium and chloride are lower, so that concentration gradients are not the only factors involved.

Phosphorus apparently penetrates the epithelium only in minute quantities, while potassium is readily absorbed from rumen liquor or aqueous solutions. Sodium and chloride can traverse the epithelium in both directions, even against a concentration gradient. Water can pass across the epithelium in quantity: hypotonic solutions placed in the empty rumen lose water, and hypertonic solutions gain water. The quantities absorbed do not increase directly with an increase in molarity, which suggests that there is a maximum rate of water flow under these conditions. The omasum is permeable to water, and it is known to concentrate phosphorus, magnesium, calcium and chloride, either by water absorption or the passage of ions across its epithelium.

The last speaker was Mr. R. J. Garner (University of Bristol), who discussed the intermediary metabolism of ruminants. Most of the carbohydrate digested is absorbed as short-chain fatty acids, all available evidence indicating that very little glucose is absorbed from any part of the alimentary tract. Of these fatty acids, propionic is the only one known to be glycogenic; it is rapidly converted into glucose in the liver, and very little enters the peripheral circulation. Acetic acid is oxidized by many tissues in both ruminants and non-ruminants, and it is also utilized for fat synthesis. The high arterio-venous differences in acetic acid concentration in the sheep's head and the cow's mammary gland indicate that it is metabolized extremely rapidly by ruminant tissues. Butyric acid is usually considered to be ketogenic, yet intravenous injection of sodium butyrate has been stated to relieve hypoglycæmic symptoms in lambs and rabbits. However, it is known that butyric acid is selectively metabolized by rumen wall, largely to ketone bodies, so that only a small proportion of the butyrate produced enters the blood.

The adult ruminant depends on short-chain fatty acids for most of its energy, and shows striking changes in its behaviour towards glucose. One of the most remarkable features of the adult ruminant is its ability to tolerate extremely low blood-glucose levels. The erythrocyte of the ruminant is relatively impermeable to glucose, so that the level of glucose in whole blood approximates to plasma levels. Even when this fact is considered, the ruminant is in a permanent state of hypoglycæmia as compared with most other species. This low blood-sugar level is accompanied by a reduced ability of ruminant tissues to utilize glucose. When injected intravenously it is removed from the blood at a much lower rate than from the blood of man or dog. In this respect the ruminant resembles a diabetic man.

Young ruminants on a milk diet have a blood-sugar level and glucose tolerance similar to non-ruminants: the appearance of adult conditions coincides with the development of rumen function. It has been suggested that it is the onset of ruminal digestion which initiates the change in behaviour towards glucose, and there is some evidence that this change can be postponed by prolonged milk feeding, withholding roughage, or including antibiotics in the diet.

The rise in blood fatty acid which follows the onset of ruminal digestion coincides with a pronounced fall in blood-sugar level, which suggests that the increased intake of these acids may be a factor. However, horses and rabbits also absorb considerable quantities of fatty acids from the cæcum, and yet remain normal in blood-sugar level and glucose tolerance. Fermentation in the rumen also leads to a fall in the amount of carbohydrate absorbed. In the non-ruminant, a high-fat, low-carbohydrate diet causes a reduction in blood-sugar level, a reduced glucose tolerance and a reduced rate of absorption of glucose from the intestine (due to a lowered hexokinase activity), a change approximating to the normal state of affairs in the ruminant.

The effect of diet on intermediary metabolism is not understood. It has been suggested that certain products of metabolism, including acetate, act as cellular regulators, shifting the emphasis in metabolism from carbohydrate to fatty acid according to nutritional conditions. Rumenal fermentation may cause the change in carbohydrate metabolism simply by altering the proportions of carbohydrate and fatty acid available to the cell. Attempts to alter these proportions absorbed by the adult ruminant have led to no observable changes in carbohydrate metabolism. The low normal blood-sugar level of adult ruminants may be a result of a change in balance between the pancreatic, anterior pituitary and adrenal hormones which regulate it. Dietary factors can affect the functional activity of the anterior pituitary and possibly of the adrenal cortex, and can also alter the sensitivity to insulin.

The foregoing evidence suggests that nutritional conditions are chiefly concerned in bringing about the observed peculiarities in intermediary metabolism and hormonal balance in ruminants. In conclusion, Mr. Garner suggested that the low blood-sugar level may be an adaptation of physiological importance in conserving carbohydrate for essential purposes.

A. G. SINGLETON

OBITUARIES

Mr. R. Burne, F.R.S.

BY the death of Richard Burne, British zoology has lost far more than the maker of minutely perfect dissections and the writer of accurate and beautifully illustrated descriptions of animal structures, whose working life was spent among John Hunter's specimens in the Royal College of Surgeons. Burne was a shy, quiet man, who avoided publicity and, probably owing to a slight stammer, rarely read papers before scientific societies or delivered lectures to students. Few really knew him well, and still fewer were in a position to appreciate his outstanding abilities as a comparative anatomist. It was not until he was in his sixtieth year that he was elected a Fellow of the Royal Society.

Burne carried the art of self-effacement to almost extreme lengths. He was always ready to credit to others the work that, as a matter of fact, he had himself accomplished. He worked in Lincoln's Inn Fields just as William Clift, more than a century before him, had done: a man whose whole purpose was the perpetuation of John Hunter's ideals as they were exemplified in his Museum. Like Clift, he had no care as to who was given the credit so long as the work was done. Burne also found a likeness to Clift in that he was at heart a Londoner who loved to seek out odd corners and old associations around Lincoln's Inn Fields and the Inns of Court. Probably some of his happiest times were spent when, in the genial company of his fellow comparative anatomist, Frederick Gymer Parsons, he wandered about the Inns of Court when the day's work was done and all was quiet in the deserted streets around the precincts of the Temple. An eminent zoologist he most certainly was; but beyond that, all those who knew him best will always remember that he was a gentle and a generous man in whom no thought of self-interest ever intruded in the work to which he devoted his life.

Richard Higgins Burne, the son of a solicitor, was born in London on April 5, 1868. He was educated at Winchester and proceeded to Oriel College, Oxford, where he graduated in natural science in 1889. For two years after leaving Oxford he worked at the Royal College of Science in South Kensington and here came under the influence of that gifted teacher Thomas George Bond Howes, who was then assistant professor of zoology and succeeded Huxley in the professorship in 1895. In 1892, Burne was appointed as anatomical assistant at the Royal College of Surgeons and started his long and faithful service to the Museum that only terminated with his retirement in 1934. Charles Stewart was conservator when Burne joined the staff, and after his death in 1907 there began the long and happy association with Sir Arthur Keith that lasted for the next twenty-three years. In 1908, Burne's office was changed to that of assistant curator and in 1912 to physiological curator.

It is impossible to over-estimate the value of Burne's work in the service of the Hunterian Museum, and had it not been for his carefully compiled descriptive catalogues of the specimens, it would have been impossible to face the task of reconstruction after the terrible losses by enemy action in 1941. The Gold Medal of the College was awarded to him in 1925 and never was it better bestowed.

Among Burne's most important published works are probably those dealing with the minute ramifications of the vascular system of certain fishes. Moreover, these papers are the most characteristic, since they are founded on the minutely perfect dissections in the preparation of which he developed such extraordinary skill. A handbook of his dissections of the Cetacea, edited by Dr. F. C. Fraser, was issued by the British Museum last year. But Burne's real life-work is embodied in the catalogues of the Hunterian Museum and in the collection of unpublished notes and drawings preserved in the College. In 1937, he was appointed a Hunterian Trustee, and until his death his advice and his vast knowledge of the contents of the Museum were invaluable during the critical years of the Second World War and after the disaster that swept away so much of his life's work.

F. WOOD JONES

Prof. L. Prandtl, For.Mem.R.S.

THE death of Ludwig Prandtl on August 15 at Göttingen has taken from the aeronautical world one of its greatest pioneers, perhaps the greatest of them all in the field of theoretical aerodynamics. He was seventy-seven years of age, having been born in 1875. He was educated as an engineer. He occupied several teaching posts before going to Göttingen in 1907, where he spent the rest of his life and inaugurated a school of aerodynamics and hydrodynamics which soon became famous throughout the world. While he will be remembered chiefly for his theoretical work, he was also a brilliant experimentalist, and he set up at Göttingen a comprehensive aeronautical laboratory which contained the first really successful return-flow wind tunnel. Prandtl had appreciated the two essential features for steady flow in such a tunnel, namely, a fine-mesh honeycomb and a rapid contraction just ahead of the working section. In this tunnel he experimented with airship models at a time when the Germans believed that the heavier-than-air type of aircraft would have a great commercial future. He also studied the drag of spheres and cylinders and was apparently the first investigator to realize the importance of stream turbulence in connexion with the critical Reynolds number of such bodies.

In the theoretical field, Prandtl's original thinking illuminated almost all the fundamental problems of aerodynamics and opened new paths to the many scientists at Göttingen and elsewhere who were able to appreciate his ideas and to follow them up. Among his earlier investigations was the study of the behaviour of an aerofoil of finite span, in which he gave mathematical precision to the ideas outlined years before in Britain by F. W. Lanchester, and showed how to calculate the effects of aspect ratio of wings, and the interference between the two wings of a biplane or between wings and tailplane. It was a long time before the full significance of this work was appreciated in Britain, perhaps because few of the original workers here had a good knowledge of German; indeed, it was not until the late Hermann Glauert translated and expounded Prandtl's papers that we began to see how great and important were Prandtl's contributions to aerodynamic theory.

It is impossible, in a brief notice, to mention all Prandtl's major contributions; one must be content to single out one or two of the most fundamental of them. He studied the flow of compressible fluids and established the basis of what has now become an investigation of immense extent and of the greatest importance in these days of transonic and supersonic flight. But perhaps his greatest contribution was his concept of the boundary layer and his brilliant mathematical treatment of it. By making certain assumptions which were approximately true in the thin layer of retarded fluid close to the surface of a body, he was able to reduce the intractable general equations of viscous flow to a form which, though still far from simple, was at least amenable to analytical solution in some cases, and to numerical integration in many more. This work led to an understanding of the phenomena underlying the drag of bodies of fine form, such as constitute the wings and fuselages of aircraft, and incidentally explained the diverse results which had been obtained in different wind tunnels in terms of differences in the transition from laminar to turbulent flow in the boundary layer. In the hands of many who have followed Prandtl's lead, we now have a fairly complete theory of aerodynamic drag which is of inestimable value to the aircraft designer.

While the highest tribute is due to Prandtl for his own original researches, no less is due to his outstanding success as a teacher and leader of thought. Among those who have passed through his hands at Göttingen are to be numbered some of the most illustrious original thinkers and research workers in the aeronautical field; to mention but one name, Theodor von Kármán, who has done so much to extend Prandtl's boundary-layer work. Prandtl received many honours in recognition of his work; in Great Britain he was awarded the Gold Medal and the honorary fellowship of the Royal Aeronautical Society, the foreign membership of the Royal Society and an honorary degree of the University of Cambridge.

With his death a very great man has passed from among us and his loss will be mourned by many who knew him personally—and by still more who knew only the value of his work—in all countries where aeronautical science is an important activity.

Ernest F. Relf

NEWS and VIEWS

Nobel Prize for Medicine and Physiology for 1953

The Nobel Prize for Medicine and Physiology for 1953 has been awarded jointly to Prof. H. A. Krebs, professor of physiology in the University of Sheffield and director of the Medical Research Council Unit for Research in Cell Metabolism, and Dr. F. Lipmann, head of the Biochemical Research Laboratories, Massachusetts General Hospital.

Prof. H. A. Krebs, F.R.S.

Prof. Krebs has mostly been concerned with the study of metabolic processes by experiments *in vitro*. The first of his two greatest contributions to biochemistry was from Freiburg in 1932, when he elucidated the mechanism of urea synthesis in the liver, by discovering the participation of ornithine, citrulline and arginine through a cyclical process—a concept of unprecedented nature. His subsequent observations on the deamination of amino-acids demonstrated D-amino-acid oxidase, and laid foundations for future studies of the L-acids. In Cambridge in 1935 he proved the synthesis of glutamine from glutamic acid and ammonia in tissue slices. After moving to Sheffield, he announced in 1937 his second major contribution, the citric-acid cycle. Before this, the path of oxidation of carbohydrate from pyruvate onward was unknown; although information was available, its significance was not appreciated. Krebs supplied the missing evidence and the idea, again that of a cycle, and the problem was solved. The citric-acid cycle has stood the test of time, requiring only amplification of detail; it is concerned with oxidation of fat and protein as well as carbohydrate, provides paths for gluconeogenesis and amino-acid synthesis, and is the chief source of metabolic energy. In recent years Krebs's laboratory has been particularly concerned with the movement of substances across biological membranes, and he has studied the uptake of glutamic acid and potassium by tissue cells, processes driven by energy from metabolism. He has also employed isotopes in the quantitative investigation of oxidative phosphorylation and ion transfer.

Dr. Fritz Lipmann

After studying problems of muscle metabolism in Meyerhof's laboratory and of fermentation in the Carlsberg laboratory, Lipmann set the pattern for his future work when in 1937 he began to analyse the oxidation of pyruvate to acetate by bacteria. He found that the oxidation is accompanied by phosphorylation, and announced from Cornell University in 1939 that the 'energy-rich' ester acetyl phosphate is an intermediate. His celebrated article "Metabolic Generation and Utilisation of Phosphate Bond Energy" (1941) organized and developed existing ideas and had the most profound influence on subsequent biochemical thought and research. Moving to Boston, Lipmann realized that acetyl phosphate is not formed in pyruvate oxidation in animal tissues; some other substance had to be sought. By a happy coincidence his own researches led to its identification. Studying the biological acetylation of sulphanilamide, he discovered a new coenzyme, coenzyme *A* (coenzyme of acetylation). Finding that it is a derivative of the vitamin pantothenic acid and a general constituent of living organisms, he quickly realized that it is of fundamental importance in carbohydrate and fat metabolism. By 1946 it was clear that some acetyl derivative stood at the entry to the citric-acid cycle, on the paths of carbohydrate and fat oxidation and ketone-body formation. The idea grew that this was the acetyl derivative of coenzyme *A*, and was confirmed after the isolation of this substance from yeast by Lynen and Reichert in 1951. In the meantime Lipmann persevered in the purification of coenzyme *A* and as a result its structure has recently been settled.

Plant Pathology at the Imperial College of Science and Technology, London :

Prof. W. Brown, F.R.S.

WITH his retirement from the headship of the Botanical Department and from his appointment as professor of plant pathology in the University of London, Prof. W. Brown severs a long association with the Imperial College of Science and Technology. A graduate in arts and science of the University of Edinburgh, he went to London to undertake his first researches at South Kensington. He afterwards carried out investigations for the Department of Scientific and Industrial Research and the Ministry of Agriculture. In 1923 he was appointed assistant professor at the Imperial College, and in 1928 professor of plant pathology. On the retirement of Prof. V. H. Blackman, Prof. Brown was invited to become head of the Botanical Department. As a scientist, he showed from the outset a penetrating insight into the problems of mycology and plant pathology. The long series of experimental studies of the physiology of parasitism carried out by him and his research students are characterized equally by a directness and simplicity of approach, and by the profoundly interesting and important results which they yielded. These investigations, with others on the growth of fungi and their variation in culture, and directly practical studies of diseases of crops, together with a teaching course both inspiring and thorough, constitute a landmark in this field of botanical endeavour. For Brown's teaching and research have not only aroused the enthusiasm of his own students but have also reached a much wider body of scholars during the past thirty years. The work published in his own name, however, gives only a meagre and partial impression of his actual achievement; for throughout the years his laboratories were thronged with research students from all parts of the world, and he gave all of them of his best without stint. His general appreciation and comprehension of the problems of plant pathology in major crops were enhanced from time to time by wide travel, both in temperate and tropical regions. His eminence in his own particular field, and in the field of scholarship generally, has been recognized by his presidency of the British Mycological Society in 1933, of the Association of Applied Biologists in 1944 and 1945, and of Section K of the British Association in 1951, and by his election to the Royal Society in 1938. At this time, Prof. Brown will be thought of with affection and respect by past students, colleagues and associates in every part of the world, and their good wishes will go with him into what it is hard to conceive of as being other than an active retirement.

Prof. P. H. Gregory

PROF. BROWN will be succeeded by Dr. P. H. Gregory, a former student and one who has himself made a distinguished career in mycology and plant pathology. After an initial education at Brighton Technical College, which he entered in 1924, Gregory undertook advanced study in the Royal College of Science in 1928, working in plant pathology under the direction of Prof. Brown. An opportunity of continuing his studies in Canada presented itself in 1931 when Gregory became attached to the Manitoba Medical College to undertake research in medical mycology under Dr. A. M. Davidson and the late Prof. A. H. Reginald Bullock. Dr. Gregory returned to an appointment in England in 1935, at Seale Hayne Agricultural College, the particular work being the investigation of diseases in outdoor horticultural crops in the south-west of England. On the outbreak of war he joined the scientific staff of the Agricultural Research Council to work on problems of potato virus diseases. In 1945 his experience was extended to industrial mycology when he was seconded to work with I.C.I. (Pharmaceuticals), Ltd., for one year to organize a research team working on penicillin and other antibiotics. Thereafter, in 1948, he was appointed to the staff of the Department of Plant Pathology at Rothamsted Experimental Station. Dr. Gregory's research has ranged widely over the fields of mycology and plant pathology. His published work, which includes some fifty scientific papers published independently and jointly, relates to plant pathology, plant virus diseases, medical and general mycology. His post at Rothamsted has given him practical experience in, and contact with, the general problems of agricultural as well as with the special problems of plant diseases. Dr. Gregory was elected president of the British Mycological Association in 1951 and edits the Society's *Transactions*, and he was formerly chairman of the Plant Pests and Diseases Committee of the Association of Applied Biologists. He will take to his new post critical judgment and powers of organization based on a wide and varied experience.

Scientific Liaison Officer in Wales :

Dr. R. O. Jone

THE Department of Scientific and Industria Research has created a new post by the appointment of Dr. R. O. Jones to be its resident liaison office in Wales. Dr. Jones took up his new duties o November 1, his office being in the Welsh Board o Health Building, Cathays Park, Cardiff. His tas will be to study the industrial position in Wales wit the view of assisting in the identification of industria problems amenable to research and in the applicatio of existing knowledge and research facilities to mee Welsh needs. To this end, he will work in clos collaboration with other government departments i Wales and with Welsh industrial and regional organizations. It is hoped to provide a link betwee Welsh firms and the research laboratories of th Department of Scientific and Industrial Research the research associations and others, and to mak more readily accessible in Wales the scientifi information already available within the Department's organization. Dr. Jones has already spen more than a year in a preliminary examination o Welsh problems in these fields. A graduate o University College, Swansea, and of King's College London, he has in recent years been a member of th headquarters staff of the Department of Scientifi and Industrial Research. Before that he was concerned in the development and utilization of non ferrous minerals, after having served for some year in the Geological Survey and Museum. He is member of the Court of the University of Wales, o the Court of Governors of the University College of South Wales and Monmouthshire, and of various educational and other bodies associated with the Principality.

The Carnegie United Kingdom Trust:
Mr. J. Wilkie

MR. JAMES WILKIE is due to retire from the secretaryship of the Carnegie United Kingdom Trust on March 31, 1954, when he will be succeeded by Mr. D. N. Lowe (*Nature*, October 31, p. 794). Mr. Wilkie became secretary of the Trust in 1939. He had to face almost immediately the disorganization caused by the War, which put a sudden stop to many of the major projects of the Trust but, at the same time, enabled useful work to be done in new fields. Wilkie helped to deal with this situation quickly and effectively, and he tackled with success and enthusiasm the Trust's scheme to help amateur choral and orchestral societies, professional orchestras and Sadler's Wells. The Trust might claim that it was for a time the 'Arts Council' of the country, and Wilkie was a member of the first C.E.M.A. committee under Dr. Tom Jones which ultimately took over, as the Arts Council, many of the concerns that had been helped by the Trust. Wilkie was always quick to react to new ideas and suggestions and to form judgments on their merits. He succeeded early in his career as secretary of the Trust in establishing most cordial relations with other Trusts and with all officials with whom he came into contact. During his time as secretary of the Trust, Wilkie has taken an active interest in different forms of social work and in the adult education movement. He has served on numerous committees and has been a valuable member of them. He has taken a great interest in many aspects of library work, and in 1951 was president of the Library Association.

Meteorological and Magnetic Survey of the Oceans

DR. B. M. CWILONG, associate professor of physics in the University of British Columbia, has just sailed from Hamble near Southampton in the *Princess Waimai*, a 48-ton 74-ft. yawl, to begin a magnetic survey of the Pacific and other oceans. For this purpose a non-magnetic vessel is required; none has been available since the American non-magnetic ship *Carnegie* was burned out off Samoa in 1929, and Dr. Cwilong has designed a small 34-ft. vessel, *Non-magnetic III*, which is nearing completion in Vancouver. The *Princess Waimai* will serve as a base-ship when the two ships join forces in Hawaii, for the survey work in the Pacific, which is scheduled to take three years. Dr. Cwilong graduated at the University of Warsaw, and later carried out research at the Warsaw Institute of Experimental Physics, specializing in spectroscopy, and at the National Meteorological Institute. He was attached as a scientist to the Polish training ship *Dar Pomorza* during 1933–34 and circumnavigated the Atlantic, and in the following year, on the invitation of the Swedish authorities, he joined the crew of the famous Swedish training four-master *Abraham Rydberg*. During the Second World War he was attached as an expert to the Polish Air Force and eventually reached Britain. He then went to the Clarendon Laboratory, Oxford, where he studied the formation of ice particles in cloud. Since the War, Dr. Cwilong has spent three years in New Zealand, as a senior lecturer in physics at Victoria University College, Wellington, and a further three in the University of British Columbia as associate professor and head of the low-temperature laboratory. Dr. Cwilong hopes to take meteorological and atmospheric electricity measurements on the first part of his voyage, to the Bahamas, and he may investigate the formation of thunder-clouds and waterspouts in the Doldrums. Part of the scientific equipment has been provided by the Air Ministry.

Royal Society of Edinburgh: Officers for 1953–54

THE following have been elected officers and members of council of the Royal Society of Edinburgh for the session 1953–54: *President*, Prof. James Kendall; *Vice-Presidents*, Prof. J. H. Gaddum, Prof. James Ritchie, Prof. R. C. Garry, Prof. W. M. Smart, Dr. A. H. R. Goldie and Prof. C. M. Yonge; *General Secretary*, Dr. J. E. Richey; *Secretaries to Ordinary Meetings*, Prof. J. Norman Davidson and Dr. T. R. Bolam; *Treasurer*, Mr. A. W. Young; *Curator of Library and Museum*, Dr. Douglas Guthrie; *Members of Council*, Prof. Norman Feather, Sir Godfrey Thomson, Dr. D. P. Cuthbertson, Principal H. B. Nisbet, Prof. T. C. Phemister, Dr. J. B. Simpson, Prof. Meirion Thomas, Dr. J. M. Cowan, Dr. David Jack, Prof. J. M. Robertson, Prof. D. Whitteridge and Prof. E. M. Wright.

Mathematics and Science Teachers in Scotland

IN *Nature* of October 24, p. 750, a note was published referring to a committee to advise the Secretary of State for Scotland on the supply of mathematics and science teachers in Scotland. The full committee is as follows: Sir Edward Appleton (*chairman*); Prof. E. T. Copson, professor of mathematics, University of St. Andrews; Prof. J. M. Graham, Lord Provost of Aberdeen; R. L. Gwilt, general manager of the Scottish Widows' Fund and Life Assurance Society, and president of the Faculty of Actuaries in Scotland; Dr. W. J. Jenkins, chairman of the Nobel Division of Imperial Chemical Industries, Ltd., Ardeer; A. G. McKimmie, head-master of Allan Glen's School, Glasgow; W. G. Marskell, superintendent of the Research Department of Babcock and Wilcox, Ltd., Renfrew; Dr. A. R. Murison, rector of Marr College, Troon, ex-president of the Educational Institute of Scotland; Dr. H. B. Nisbet, principal of Heriot-Watt College, Edinburgh; J. N. Toothill, general manager of Ferranti, Ltd., Edinburgh; H. P. Wood, director of studies, Jordanhill Training College, Glasgow; and A. L. Young, director of education, Aberdeenshire. A. G. Roger and J. B. Beaumont, Scottish Education Department, have been appointed assessor and secretary respectively to the Committee. Communications in connexion with the Committee should be addressed to the Secretary, Committee on the Supply of Teachers of Mathematics and Science, St. Andrew's House, Edinburgh 1. The terms of reference of the Committee are: "to consider and report on the causes and effects of the present and prospective shortages of teachers of mathematics and science in Scottish secondary schools and to suggest remedies". The Committee will maintain liaison with the National Advisory Council, which deals with the supply of teachers in England and Wales, and with the Advisory Council on Scientific Policy, which advises the Lord President of the Council in the exercise of his responsibility for the formulation and execution of Government scientific policy.

Myxomatosis Advisory Committee

In reply to a question in the House of Commons on October 29, Sir Thomas Dugdale, Minister of Agriculture and Fisheries, stated that he and the Secretary of State for Scotland have set up the following committee to advise on the problems arising in connexion with myxomatosis in rabbits and the action that should be taken by the Government: Lord Carrington (*chairman*), Lord Dundee, Lord Merthyr, Dr. C. H. Andrewes, H. Collison, Dr. J. W. Evans, Prof. R. E. Glover, H. Gardner, J. Scott Henderson, the Hon. Mrs. George Lane, C. T. Plumb, J. N. Ritchie, J. C. Sandford, W. H. Senior, Major R. Verney and Harold Woolley. He added that all reasonably practicable steps are being taken to stamp out the only two known outbreaks of the disease that have recently come to light in Kent. Measures are also being examined for the protective inoculation of tame rabbits in case myxomatosis should spread. Future policy will be determined in the light of recommendations from the new Advisory Committee, which is meeting immediately.

Scottish Postgraduate Scholarships in Agriculture

The Department of Agriculture for Scotland has awarded the following postgraduate scholarships in agricultural subjects, tenable for periods up to three years, at the institute shown: *Husbandry*, Q. Brown and P. M. Bremner (School of Agriculture, Cambridge), W. J. Donald, N. C. Lawson and T. M. Sutherland (University of Reading); *Agricultural Engineering*, J. Roddan and J. H. S. Torrance (King's College, University of Durham). The current awards of the following have been continued: *Husbandry*, J. Eadie (University of Edinburgh), D. Stuart Hay (University of Wisconsin), R. Laird (Ohio State University), T. D. MacLean (University of Reading), and R. R. Shepherd (Rhuakura Animal Research Station, Hamilton, New Zealand); *Agricultural Economics*, A. V. Vickery (Agricultural Economics Research Institute, Oxford).

International Botanical Congress, 1954

The International Botanical Congress to be held in Paris in July 1954 will include, among its sections, one dealing with phycology. The preliminary programme of its meetings includes comparative cytology and biochemistry in relation to classification, algal life-cycles, classification of Chlorophyceae, algal evolution in relation to the origin of vascular plants, fossil algae, ecology and geographical distribution of marine and freshwater algae. Special excursions, in relation to marine and freshwater algae, are planned both to precede and follow the congress. Summaries of original communications, not exceeding two hundred words in length, should be sent to Prof. Feldmann (marine) or Dr. P. Bourrelly (freshwater), at the Institut Oceanographique, 195 rue St. Jacques, Paris 5, before January 15, 1954.

International Congress of Genetics

At the final session of the International Congress of Genetics recently held at Bellagio, Italy, the following resolution was unanimously passed: "The Congress asks the International Committee not to recommend that the next Congress be held in any country to which it may be expected that scientists would be refused permission to enter on grounds of race, nationality, religion, place of birth, or political associations past or present".

Announcements

Dr. Harold King, C.B.E., F.R.S., late chemist to the Medical Research Council, has been awarded the Addingham Gold Medal for 1952 by the trustees of the Wm. Hoffman Wood Trust for his work on the curares and the decamethonium compounds leading to the relief of pain and suffering in humanity.

Mr. Charles Biddolph is retiring in December from the post of senior technician, after forty-seven years service in the Department of Zoology, King's College, London. Former students and members of staff are invited to attend a dinner to be given in his honour on December 11. Those wishing to attend should write to Dr. M. E. Brown, Department of Zoology, King's College, London, W.C.2, by November 25.

Sir Roger Duncalfe, chairman of British Glues and Chemicals, Ltd., has been elected president of the British Standards Institution in succession to Viscount Waverley, whose three-year term of office has ended.

Mr. Henry S. Darling has been appointed as head of the Hop Research Department of Wye College (University of London), near Ashford, Kent, and will be taking up his duties in April next year. Mr. Darling, who is a graduate of Queen's University, Belfast, is at present senior lecturer in zoology in the Faculty of Agriculture of the University College of Khartoum, having previously served with the Insect Infestation Division of the Ministry of Food, with the Middle East Anti-Locust Unit, as entomologist in the Research Division of the Department of Agriculture in Uganda and also in a similar capacity with the Sudan Ministry of Agriculture.

The Meldola Medal, which is the gift of the Society of Maccabaeans and is normally given annually, is being offered for award early in 1954 to the chemist who, being a British subject and less than thirty years of age on December 31, 1953, shows the most promise, as indicated by his or her published chemical work brought to the notice of the Council of the Royal Institute of Chemistry before December 31. Communications should be addressed to the President, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1, the envelope being marked "Meldola Medal".

The autumn general meeting of the Iron and Steel Institute will be held in the offices of the Institute (4 Grosvenor Gardens, London, S.W.1) during November 24–25 and will be followed on the afternoon of November 25 and the whole of the succeeding day by a symposium on the process of sintering. Further information can be obtained from the Secretary of the Institute at the above address.

The third international congress of Alpine meteorology will be held in Davos, Switzerland, during April 12–14, 1954. The four topics to be considered in detail at the meeting will be synoptic meteorology, radiation, bioclimatology, and snow and ice. Davos is the most important climatic station in Switzerland and is the site of two important institutions: the Physico-Meteorological Observatory, Davos-Platz, and the Federal Institute for the Study of Snow and Avalanches, Weissfluhjoch-Davos. Those wishing to read papers should write as soon as possible to Dr. W. Mörikofer, Observatoire physico-météorologique, Davos.

ANTICHOLINESTERASES

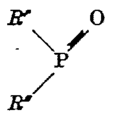
A SYMPOSIUM on "Anticholinesterases", jointly arranged by the British Pharmacological Society and the Fine Chemicals Group of the Society of Chemical Industry, was held in the lecture theatre of the Wellcome Foundation, London, during March 27–28. The symposium was divided into four sessions, at the first two of which the chemical features of anticholinesterases which confer inhibition and the mode of their action *in vitro* were discussed, and for the third and fourth sessions the acute effects and the chronic effects, respectively, in the mode of action *in vivo* were considered. The full text of the contributions will be published in due course by the Society of Chemical Industry.

Chemical Features which confer Inhibition : Structure Action Relations

Prof. J. H. Gaddum gave a historical review of the discoveries of anticholinesterases, starting with the first known one, eserine or physostigmine, which was originally obtained from the ordeal beans used in Old Calabar in Nigeria for the trial of witches. When one native accused another of being a witch, a council of chiefs was summoned and the accused was asked to state his case. The usual reply was a demand for trial by ordeal, which took place in public and was watched by a crowd of onlookers. The accused swallowed the beans, either as the dry kernel or in the form of an infusion. If this produced vomiting, the prisoner was acquitted and the accuser might be made to go through the same ordeal. Those whose consciences were clear were confident of their ability to vomit and were more likely to do so than those with guilty consciences who ate slowly and without confidence so that they absorbed the poison and died. According to T. R. Fraser (1862) about a hundred and twenty natives died in this way each year out of a population of about a hundred thousand. The beans were brought to Europe in 1840 and first investigated by Sir Robert Christison, who was professor of materia medica in Edinburgh at that time.

Prof. Gaddum divided the anticholinesterases into three groups : drugs allied to eserine which combine reversibly with the enzyme ; active organic phosphates the actions of which are irreversible *in vitro* ; and drugs like octamethylpyrophosphoramide ('Ompa'), which are not active by themselves but are converted into active, organic phosphates in the body.

After this introduction, Mr. A. H. Ford Moore concentrated on compounds containing phosphorus. He outlined their development from derivatives of phosphofluoridic acid, culminating during the Second World War in the discovery of high activity of the di-*iso*propyl ester, di-*iso*propyl fluorophosphonate. At the same time, work had progressed in Germany, where Schrader had found that certain derivatives of phosphoramidic acid show insecticidal properties. On the basis of these two types, further developments have taken place, and Mr. Moore summarized the present-day structure–activity relationship in this field by pointing out that a residue



is essential, as suggested by Schrader, together with an acyl group. The R' is preferably an alkoxy group, while the R'' can be an alkylamino group, another alkoxy group, a methyl group, and so forth. The so-called acyl group can be a fluorene, a nitrile, another phosphate radical, etc. It is only necessary that, at the moment the compound comes into contact with the enzyme, the acyl group is removed and the group containing the phosphorus attached to a specific group of enzyme.

Mr. A. W. D. Avison considered anticholinesterases containing at least one aromatic ammonium group, and using the concept developed by Bergman, Nachmansohn, Wilson and others—namely, that the true enzyme possesses at least one grouping called the anionic side which is capable of reacting with the ammonium group, and another called the esteratic side reacting with carbamate, and possibly identical with the grouping reacting with the phosphorus-containing drugs—he gave a complete review of the work in this field, starting with the basic contributions by Stedman and Stedman and continued by Aeschlimann and Reinert with their discovery of prostigmine. Mr. Avison then touched upon further variations, particularly on substances, mentioned later in the discussion by F. C. Copp, which have two quaternary ammonium groups in one molecule, and on those claimed by Funke, Depierre and Krucker to be many times more active than other drugs in this field. He also mentioned the phosphostigmines having ammonium groups and dialkylphosphate groups, the latter in place of the carbamate.

In the discussion, Drs. G. S. Hartley and B. C. Saunders referred to the phosphorus-containing compounds, while Drs. A. L. Morrison and F. A. Atherton divided their attention between the ammonium- and phosphate-bearing substances. Finally, K. Bulloch, who had investigated the series of alkylating cytotoxic substances including nitrogen mustards, confirmed indirectly the present-day specificity of aromatic quaternary ammonium compounds with carbamates or phosphates or phosphorus-containing substances as the most potent anticholinesterases, because none of his substances mentioned possesses any remarkable anti-enzyme activity.

In summing up the first session, Prof. F. Bergel pointed out that the over-all impression gained was the presence of two sites in the cholinesterase, at least in the true cholinesterase, with which the drugs make contact : an 'anionic' group which reacts with the quaternary ammonium groups of the inhibitors ; and an 'esteratic' group which combines with the O-acetyl of acetylcholine or with the carbamate groups of the 'stigmines'. This group is also the one which undergoes phosphorylation by the phosphorus-containing anticholinesterases. Looking at a future working programme, further studies of the purification of the cholinesterases would be desirable. It would also be useful to have a definite estimate of the stoichiometry relation between drugs and enzymes, and to carry out tests with substances which have two or more phosphate groups or three or more ammonium groups in the same molecule, if possible at the right distance, as indicated by present speculations on the enzyme structure.

Mode of Action of Anticholinesterases *in vitro*

The chairman, Dr. E. Stedman, pointed out some of the anomalies in the nomenclature of the cholinesterases, and later in the discussion Mr. W. K. Berry brought out some of the difficulties of fitting all the cholinesterases into the classical 'true' and 'pseudo' types.

The general theme which emerged from this session of the symposium was that the following general reaction may represent the steps involved in the hydrolysis of substrates and the inhibition by reversible inhibitors such as prostigmine, etc., or by organo-phosphorus compounds: $E + A_{(x+y)} \xrightarrow{(1)}$

$$[E - - - A_{(x+y)}] \xrightarrow{(2)} A_y + E - - - A_x \xrightarrow[+H_2O]{(3)} E + A_x$$

where E is cholinesterase, A the substrate, etc., and x and y are the acid and alcohol groups of ester.

After pointing out many of the experimental difficulties in studying the inhibition of physostigmine, prostigmine and related compounds, Dr. F. Hobbiger showed that these inhibitors are hydrolysed at their ester group. However, reaction (3) is slow, while reaction (1) is fast, so that the enzyme is inhibited. This point was further elaborated in the discussion by Dr. H. O. Michel, who described some of his work with high enzyme and inhibitor concentrations. Under these conditions the increase in activity obtained upon dilution is mainly due to the progress of reaction (3) rather than to the reversal of reaction (1). Dr. Hobbiger also pointed out that inhibitors with no ester group, such as choline, are true reversible inhibitors since reactions (2) and (3) are not involved. In discussing the organo-phosphorus inhibitors, Dr. W. N. Aldridge showed that these substances are not specific inhibitors for cholinesterase but are general inhibitors for enzymes possessing carboxylic esterase activity. The evidence available was shown to be in agreement with the view that cholinesterase is phosphorylated during inhibition—that is, reactions (1) and (2) are fast, while reaction (3) is very slow. The high energy of activation associated with the return of enzyme activity after inhibition with dimethyl *p*-nitrophenyl phosphate is in agreement with such a process. The factors discussed which affect inhibition and the return of enzyme activity included the properties of the particular enzyme, the stability of the inhibitor and the particular groups (other than the labile group) attached to the phosphorus atom. Dr. Aldridge also compared the inhibitory process for cholinesterase in relation to the enzymes which hydrolyse organo-phosphorus compounds rapidly.

Finally, Dr. B. A. Kilby discussed the metabolic conversion of certain organo-phosphorus compounds into anticholinesterases. Octamethylpyrophosphoramide ('Schradan') has little *in vitro* activity against cholinesterase, but after injection into mammals the animal dies with symptoms of acetylcholine poisoning. Evidence was given that 'Schradan' is converted *in vivo* to a powerful anticholinesterase, and the theory that this conversion involves amine-oxide formation was examined. The evidence for the metabolic conversion of diethyl *p*-nitrophenyl thiophosphate (parathion) to a more active inhibitor was also reviewed. This aspect was extended in the discussion by Dr. J. C. Gage, who showed the results of his experiments indicating that it is converted to the highly active diethyl *p*-nitrophenyl phosphate (paraoxon, *E*.600). There is, however, no information about the enzyme systems involved in these oxidations.

In summing up the session, Dr. H. Blaschko referred to the usefulness of the Wilson–Bergmann model of cholinesterase in the analysis of the different types of anticholinesterases. He hoped that the specific inhibitors might help in the understanding of the biological significance of the various cholinesterases. The recognition that coenzyme A is of importance in acylation reactions other than acetylations makes it possible that compounds like succinylcholine or benzoylcholine may be the normal substrates of those cholinesterases which are not specifically involved in the metabolism of acetylcholine.

Mode of Action of Anticholinesterases *in vivo*: Acute Effects

The chairman of the third session, Dr. W. Feldberg, reviewed the factors which determine the symptomatology of the anticholinesterases. First, they may have side actions which are not due to inhibitors of cholinesterase. Second, although the most striking effects resulting from inhibition of cholinesterase are those due to accumulation of acetylcholine, there may be other changes either in the function of cholinergic nerves or in the reactivity of the effector structures resulting from the fact that the products of hydrolysis, choline and acetic acid, are no longer available at the site of acetylcholine liberation. Finally, the symptoms of inhibition of cholinesterase may vary according to the properties of a given anticholinesterase, whether it inhibits selectively the pseudo or the true cholinesterase, whether it is soluble in water, or in lipoid media or in both and in what proportion, and whether it is hydrolysed in water or inactivated in the body by some other means. Referring to the terminologies proposed for the two groups or families of cholinesterases, Dr. Feldberg stressed that, from the physiological point of view, the terms 'pseudo' and 'true' cholinesterase, which are generally accepted in Britain, are more satisfactory than any other so far proposed, and he hoped that no new terminologies would be introduced before we know the physiological substrate or substrates of the pseudocholinesterases.

The following speaker, Dr. H. Cullumbine, pointed out that failure of respiration is the predominant factor for the lethal effects of anticholinesterase. He gave a detailed analysis of the importance of bronchospasm, neuromuscular block and central depression of respiration for the various anticholinesterases. The important role of central failure was stressed, and its possible mechanisms were discussed.

Dr. J. M. Barnes then reported on the effects of repeated doses of some anticholinesterases in anaesthetized dogs, rabbits and rats. The animals may be saved from the effects of an otherwise lethal dose of paraoxon (*p*-nitrophenyl diethyl phosphate) by a short period of artificial ventilation and will then withstand further doses of the inhibitor without respiratory effects. He then discussed the relation between neuromuscular block and inhibition of cholinesterase on the isolated rat diaphragm, and the relation between enzyme inhibition and the occurrence of irregular movements in the isolated diaphragm and in the whole rat.

Dr. M. Parkes was concerned with the protective effect of atropine and hexamethonium against the toxic effects of neostigmine and tetraethyl pyrophosphate (TEPP). Further, from his findings in guinea pigs that decamethonium and succinylcholine produce neuromuscular block which can be relieved by neostigmine and 'Tensilon' but not by tetraethyl pyrophosphate or di-*iso*propyl fluorophosphonate, he infers that the simple explanation of the anticurare effect of anticholinesterase drugs is not entirely adequate.

In the discussion, Dr. F. Hobbiger compared the *in vitro* and *in vivo* activities of the anticholinesterases tetraethyl pyrophosphate, and tertiary and quaternary aminophenyl-, quinolyl- and dialkyl phosphates. He discussed the relation between *L* 50 *in vitro* and *D* 50 *in vivo*, the duration of action as a function of the dialkyl side-chain (the duration increases with the length of the chain) and reactions not due to cholinesterase inhibition. Dr. W. L. M. Perry discussed experiments on the output of acetylcholine from the perfused superior cervical ganglion of the cat, which lead him to believe that the choline formed from the acetylcholine released by preganglionic nerve stimulation is immediately resynthesized to replenish the stock of acetylcholine 'available' for release. In the presence of eserine, hydrolysis of acetylcholine is prevented and the failure to form choline is suggested as the cause for the fatigue which occurs under these conditions in the transmission in autonomic ganglia. Another interesting observation was reported by Dr. E. J. Zaimis. She has found that, after neostigmine, even when used in very small doses, it becomes necessary to increase the voltage applied to a motor nerve in order to obtain a maximal response from the muscle. This effect is not explained by inhibition of cholinesterase and suggests that neostigmine may interfere directly with the permeability changes which occur during activity in the nerve membrane.

Next, Dr. M. Pickford described the use of di-*iso*propyl fluorophosphonate in order to obtain information about the chemical transmission of nerve impulses in the supraoptico-hypophyseal system of the hypothalamus. When injected among the supraoptic cells of both sides into dogs, di-*iso*propyl fluorophosphonate caused oliguria or anuria, followed by a period of polyuria lasting for several days—in other words, a transient diabetes insipidus. During this period, intravenous injections of acetylcholine did not produce their usual oliguric effects. From these and other findings Dr. Pickford could conclude that acetylcholine is the transmitter of at least one group of nerve fibres impinging on the supraoptic nerve cells. The problem discussed by Dr. J. Duff concerned the occurrence of acetylcholine in blood of atropinized animals after injections of paraoxon and the correlation, or lack of correlation, between acetylcholine levels of blood and the insensitivity which develops with successive injections of this anticholinesterase. Dr. J. Elkes reported on the effects of intraperitoneal injections in rats of tetraethyl pyrophosphate, di-*iso*propyl fluorophosphonate and Nu 1250 on the cholinesterase inhibition in different parts of the brain. With tetraethyl pyrophosphate, inhibition never exceeded 62 per cent in any part; with the two other inhibitors there was greater inhibition (70 per cent) in the midbrain than in any other brain region, but the unequal distribution was only seen when the doses given were not too high, otherwise inhibition became more uniform.

Dr. A. Todrick discussed the effects of thirty antagonists of acetylcholine on the cholinesterases of rat tissue. Curariform drugs were found to be mainly inhibitors of the true cholinesterase, parasympatholytic drugs mainly of the pseudocholinesterase, but Dr. Todrick said that he did not want to suggest that this difference is responsible for the pharmacological effects of these substances. Mr. D. K. Meyers's contribution concerned the problem of whether the pseudocholinesterase is responsible for destruction of acetylcholine in the intestinal wall. From his experiments with Dr. Admiral, in which the inhibition of true and pseudocholinesterase by different inhibitors was correlated with the motor activity produced in the intestinal wall, the conclusion was reached that the pseudocholinesterase does not take this role in the intestinal wall but that the enzyme responsible is the true cholinesterase, partial inhibition of which is sufficient to lead to symptoms of acetylcholine accumulation.

In summing up this session, Sir Charles Lovatt Evans pointed out that biochemical studies have not provided all the answers that are wanted. The classification of enzymes concerned in the hydrolysis of acetylcholine and other esters is puzzling in the extreme, and it is clear that the distinction into true and pseudocholinesterases by no means gives the full picture. The physiologist always hopes that pharmacological agents may provide tools for a physiological analysis finer than is possible by other means of approach, and there were examples in the symposium of that type of investigation. He said that he would like to see in such investigations a clear distinction between the effects of agents which paralyse alternatively either the true or the pseudo type of cholinesterase, however vague the various sub-types might be. The rather indefinite functions of the pseudo type might thus be made out. His own experiments with the submaxillary glands have indicated that the inactivation of the pseudo type of enzyme has but little effect, as compared with the effects of agents which inactivate the true enzyme, or both enzymes. Unfortunately those agents which inactivate the true and have very little effect on the pseudo enzyme are very easily reversible, so that the effects are difficult to localize. He wondered whether some of the data which have been obtained from the perfused ganglia should not be repeated with some other agent less easily reversible than eserine, which is the one usually employed, and with some other tissues or organs, if suitable ones could be found.

Mode of Action of Anticholinesterases *in vivo*: Chronic Effects

The chairman for the fourth session, Prof. G. R. Cameron, reminded his audience that the investigation of chronic toxicity is still one of the most difficult and uncertain problems in the field of toxicology for three very good reasons: clinical changes are almost invariably unpredictable, there being no evidence of any correlation between the chemical structure, physical characteristic and toxic effect that can be made use of; on account of the latent period which may elapse before clinical and other features become apparent; and on account of the insidious nature of chronic toxic action.

In so far as the latter is concerned, a wide variety of changes may be induced ranging from vague ill-health, anæmia, growth and metabolic disturbances to carcinogenesis. The subject is also made difficult because of the lack of a short-cut to the assessment of toxic effects. At present we have to depend upon prolonged animal experiments or astute clinical diagnosis. For that reason Prof. Cameron urged upon chemists interested in this field the necessity of working out simpler methods for the assessment of dangerous effects.

Following Prof. Cameron, Prof. A. Wilson discussed the chronic muscarinic, nicotinic and central effects of di-*iso*propyl fluorophosphonate in normal subjects and compared the effects of this substance and neostigmine in patients with myasthenia gravis and the changes accompanying these effects in the cholinesterase levels of blood. He reported, further, on the effects of di-*iso*propyl fluorophosphonate on the central nervous system of normal subjects and of patients with functional psychoses. Dr. L. Bidstrup and Dr. J. A. Bornell then gave a detailed description of the paralysis which occurs in patients poisoned by the two cholinesterase-inhibitors tri*ortho*cresyl phosphate (TOCP) and *bis* (mono*iso*propylamine) fluorophosphine (mipafox).

Poisoning by tri*ortho*cresyl phosphate has been known for many years and was the cause of the well-known ginger paralysis which occurred in the United States of America in 1930; several thousand people were affected and there were some deaths. In these cases gastro-intestinal symptoms were followed after a latent interval of two to three weeks by peripheral neuritis and led in many cases to permanent disability due to lesions in the central nervous system affecting particularly the pyramidal and cerebellar tracts of the spinal cord.

In the search for new organic phosphorus compounds which would be effective as insecticides but less toxic than parathion and other related substances already in use, *bis* (mono*iso*propylamine) fluorophosphine was discovered. Three people employed on the manufacture of a small quantity of this compound by a pilot process developed the symptoms and signs of acute organic phosphorus poisoning. Two developed paralysis in the third week after the acute episode.

Both tri*ortho*cresyl phosphate and *bis* (mono*iso*propylamine) fluorophosphine are selective inhibitors of pseudocholinesterase and were found to cause demyelination; the lesions in the central nervous system of man in poisoning by the latter are confined to the pyramidal tracts, whereas in poisoning by the former the spino-cerebellar tracts are affected as well and there are lesions in the cerebellum. It is, however, the opinion of Dr. Bidstrup and Dr. Bornell, based on the clinical findings and electromyographic studies in the cases of poisoning by *bis* (mono*iso*propylamine) fluorophosphine, that the central nervous system damage and peripheral nerve lesions are secondary to prolonged failure of conduction at the neuromuscular junctions.

The demyelination was discussed in detail by the next speaker, Dr. F. A. Denz, who reported on these pathological changes in peripheral nerves and in the central nervous system in various species. The tracts affected vary in different species. The lesions were obtained with tri*ortho*cresyl phosphate, di*iso*propyl- and diethyl-fluorophosphonate and with *bis* (mono*iso*propylamine) fluorophosphine. The problem was discussed whether the primary effect is on the myelin sheath or on the axon, and why some tracts are affected and others not. In the chicken the same tracts are involved as in beriberi. Closely connected with this problem were the following contributions given by Prof. R. H. S. Thompson and Dr. A. N. Davison. Prof. Thompson showed that the paralysis produced by tri*ortho*cresyl phosphate is not due to inhibition of true cholinesterase at the motor end-plate, as originally suggested by Bloch. The demyelination can also not be fully explained by inhibition of pseudocholinesterase, because when using other selective inhibitors of this enzyme (for example, *iso*octamethylpyrophosphoramide), although inhibition of the central nervous system of the experimental animals was as strong as after tri*ortho*cresyl phosphate, demyelination did not occur. Similarly, Dr. Davison, based on his results obtained with cholinesterase-inhibition of the central nervous system of birds by tri*ortho*cresyl phosphate, *bis* (mono*iso*propylamine) fluorophosphine and *iso*octamethylpyrophosphoramide, came to the same conclusion that prolonged inhibition of pseudocholinesterase does not appear to be a prerequisite for demyelination. Complete inhibition and subsequent fast recovery of the cholinesterase activity could be produced by the demyelinating compounds tri*ortho*cresyl phosphate and *bis* (mono*iso*propylamine) fluorophosphine, as well as by the non-demyelinating compound *iso*octamethylpyrophosphoramide. Judged by their effects on the pseudocholinesterase of the central nervous system, these compounds are apparently indistinguishable. Tri*ortho*cresyl phosphate is different in that it produces a prolonged fall in pseudocholinesterase activity. It also differs, together with *iso*octamethylpyrophosphoramide, in not producing any acute symptoms during the first few days after injection. Furthermore, it has not been possible to produce paralysis in the rat, despite prolonged and complete inhibition of pseudocholinesterase. The mechanism underlying demyelination thus remains obscure; but it is interesting and probably significant that, so far, only selective inhibitors of pseudocholinesterase have produced such late lesions in the central and peripheral nervous system.

In the subsequent discussion Dr. G. S. Hartley pointed out that the two organo-phosphorus compounds with which the late development of paralytic effects has been most clearly established are at opposite ends of the scale of water- and oil-solubility. *Bis* (mono*iso*propylamine) fluorophosphine is the most completely water-favourable of all the compounds examined, and tri*ortho*cresyl phosphate the most completely lipophilic. Dr. Aldridge's indication that the latter substance is first converted by the body into another compound may throw some light on this apparent anomaly. Prof. Biggart's closing remarks dealt with the medical and pathological aspects of the anticholinesterases, and he pointed out some of the pertinent, unsolved problems.

RATIONS FOR LIVESTOCK IN BRITAIN

THE Scottish Group of the Nutrition Society organized a conference on "Problems in providing Rations for Britain's Livestock", which was held in Aberdeen, centred on the Rowett Research Institute, during October 1–2. Prof. R. G. Baskett was in the chair, and papers were read by J. N. Aitken, A. S. Barker, S. Bartlett, K. J. Carpenter, J. A. Crichton, J. Duckworth, A. Eden, W. S. Ferguson, W. Holmes, H. R. Humphries, W. R. Muir and K. L. Robinson.

The time of the conference was opportune, for domestic and foreign trade in feeding stuffs and compounds has largely passed out of the control of the Ministry of Food and back to the hands of private traders. The Ministry's regulations no longer control the types of feeding compounds that can be manufactured or the kinds and amounts of ingredients that can be included. In addition, the use of certain antibiotics as growth stimulants in stock feeding has recently been legalized.

Circumstances have changed since farmers and compounders were last free to buy feeding stuffs and to use their skill and experience to combine them into balanced rations for farm stock. Since then the feeding stuffs moving through the channels of international trade have changed in volume, supplies of some remaining abundant, supplies of others being greatly diminished. Even trading in exportable surpluses that are plentiful is not free from difficulty, since the official policies of foreign countries burdened with these commodities are not materially affected by relaxation of controls in Britain. Such problems that faced the Ministry of Food have not disappeared with the return of trade to private hands.

The pattern of Britain's agriculture has changed since pre-war days. With more intensive use of land and greater domestic production of feeding stuffs, with greater numbers of livestock and their greater reliance on home-grown feeds, many feeding problems are different from those before the War. But none of these problems has been neglected. After the first abrupt changes in 1939 other changes came gradually, and as problems have become apparent research has developed in directions dictated by them.

Early in the conference the trends in supplies of feeding stuffs in the international markets were examined. Supplies of cereals are good and likely to continue to be reasonably plentiful. Supplies of protein concentrates are poor, and likely to remain so. Emphasis was rightly placed on the limitations of current knowledge about the nutritive values or feeding potentialities of many protein-rich plant by-products, it being recognized that scientific knowledge is extensive only so far as soya bean and groundnut meals are concerned.

Emphasis was placed on the contribution that grass and grassland products can make to solving present and future feeding problems. Grass is the most important single crop in Britain, already providing between 65 and 70 per cent of the energy needed by the nation's livestock together with important amounts of protein, while remaining the cheapest source of these nutrients. There remain great opportunities for increase in grass yield per acre on many farms.

It was recognized that mastery over grass production is easier to attain than efficient use of the crop as it grows in the field. The first step towards greater efficiency is the correct combination of strip grazing of properly manured grass (the herd being restrained by electric fencing) with conservation of the excess grass for winter feeding. By full exploitation of grass throughout the year, important quantities of feed, and especially of protein concentrates, can be saved in the dairy herd. These are then available for pigs and poultry.

Difficulties in such intensified management of grass were frankly stated. Most important of all is the effect on farmers and farm workers of the monotonous nature of daily work on a dairy farm based on high grass production. Also, various diseases appear to be closely linked to the feeding of young, highly nutritious grass, although they can be largely controlled by careful management. Again, in some areas, grass is not a reliable crop, whereas in others it offers to farmers a greater security against adverse weather.

In addition to the savings in concentrates that the greater use of grass permits in the milking herd, the prospects of economy in rearing replacements for the herd were also examined. Special attention was given to the results now coming forward from studies of one-egg twin heifers reared on different planes of nutrition. In spite of the slow growth they permit, low planes of rearing have practically no influence on final size at maturity; and although the onset of first œstrus is delayed by about three and a half months, subsequent fertility is not affected. On changing animals from a low plane of rearing to a high plane, there is a rapid increase in growth-rate, and heifers reared on low planes of nutrition gain rapidly in weight during the first lactation. Milk yields of animals reared on low planes of nutrition are somewhat lower in the first lactation, and to a lesser extent in the second. Economy in costly winter feeding can be practised with safety, provided that good summer grazing is available; but if heifers are to be bred in mid-winter to calve the following autumn, it may be necessary to provide a generous winter ration to ensure early fertility.

Economies in the feeding of pigs and poultry were seen as a problem in securing a more efficient use of protein concentrates, and particularly in devising rations that would allow the deflexion of scarce and costly animal by-products to those animals that need them most: to breeding stock and young stock. It is now possible, without using any supplements of the 'animal protein factor', to make rations exclusively from plant sources that will meet all the needs of pigs from 90 lb. live weight to bacon weight and of birds throughout the laying year, provided the eggs are not to be used for hatching. Under British conditions it is much less difficult to meet the needs of these stock for vitamin B_1, than for riboflavin, widespread deficiency of riboflavin existing in many flocks of breeding birds. Small economies can be made in the use of feeding stuffs in rearing bacon pigs by following a system of restricted feeding; but such savings are made largely at the expense of prolonged rearing times—that is, at the cost of greater labour and overhead charges. Only limited savings of concentrates could be made by the use of herbage in feeding bacon pigs.

Stress was placed on the need for more information about the energy that common feeds can provide for poultry and about many protein concentrates used in practical pig and poultry rations. As a guide to the energy value of feeds, the crude fibre-content is known to be unreliable; but little research is directed to finding analytical methods that will give a better prediction of the amount of energy that non-ruminants can extract from feeds and put to productive use. More active research is developing in the field of assessing the supplementary value of protein-rich concentrates in rations, and this is leading to a better understanding of the nutritive value of traditional protein sources. Less-known products, such as the meat meal, grax and condensed solubles, produced by the Antarctic whaling industry, are under special study, not only to determine the value of existing products but also to aid in the improvement of whale processing on factory ships and at shore stations so that minimal damage is done to this important source of extra protein for pig and poultry feeding.

The stimulation of growth and the savings in feed that are the possible results of fortifying a ration with antibiotics were also discussed. The picture continues to be indistinct. Where a condition exists for an antibiotic to exert a therapeutic effect, a spectacular result will be observed. In carefully controlled experiments small advantages will usually be found. In practical trials on farms the response to antibiotics is extremely variable, but farmers may choose to pay for the safeguard that an antibiotic can give.

The conference concluded with a discussion of the role of the agricultural adviser who links the research worker and the practical farmer. There was frank recognition of difficulties that must continue to face those whose task it is to translate the new findings of research stations into profitable practices on the farms in Britain, where the farming systems are so diversified.

JOHN DUCKWORTH

MIXING OF THICK LIQUIDS, PASTES AND SLURRIES

IN a recent report of the Committee on Chemical Engineering Research of the Department of Scientific and Industrial Research, it was pointed out that the general subject of mixing is one which would profit by more fundamental research. Although the mixing of thick materials is a matter of considerable industrial importance, there is virtually no basic information about such mixing problems, and most mixing machines have been designed by intuition and the use of empirical methods. On September 25 the British Society of Rheology organized in London a symposium on the "Mixing of Thick Liquids, Pastes and Slurries", in the hope of collecting what information is available and of clarifying the more important scientific aspects of the subject.

The symposium was opened by Mr. P. V. Danckwerts (Department of Chemical Engineering, University of Cambridge) with a paper on "General Aspects of Mixtures and Mixing". This excellent introduction to the subject first considered how the extent of mixing could be measured quantitatively. For this purpose Mr. Danckwerts introduced the concept of a 'scale of scrutiny', which he applied to the minimum size of the regions of segregation in the mixture which would cause it to be regarded as imperfectly mixed for specific purposes. The goodness of mixing could be characterized by two factors: the 'scale of segregation' is a measure of the size of the regions of segregation, or 'clumps' of the unmixed components, in an imperfect mixture, while the 'intensity of segregation' is a measure of the departure of the composition from the mean value, averaged over all the points in the mixture. Some proposed experiments were described on the mixing of two differently coloured pastes, where the number of intersections per unit length appearing along a cut section of the mixed material would provide a measure of the scale of segregation. For thick pastes the intensity of segregation will be equal to unity.

Mr. Danckwerts then suggested that dimensional analysis could help considerably in simplifying the mathematical approach to mixing problems. For the mixing of two Newtonian liquids of the same viscosity, the intensity of segregation can be expressed as a function of seven variables, but by use of dimensional analysis this can be reduced to four dimensionless groupings of variables. Some of these groupings represent important properties of the state of the system, such as Reynolds, Froude and Schmidt numbers, while others can be given a physical significance such as 'number of clumps'. These concepts may be of considerable use in 'scaling up' results from models to larger mixers. When mixing liquids of unlike viscosities, many more complications are introduced, and for Bingham solids a dimensionless grouping corresponding to a 'stiffness factor' must be introduced.

Mr. E. H. Jones (British Cotton Industry Research Association) next gave a short paper on "The Preparation of Pastes of Starch and Certain Gums for use in Textile Materials". The property of 'weavability' is imparted to textile threads before weaving, by treating with a sizing solution. The amount of size taken up by the threads as they pass through the solution depends largely on the viscosity of the sizing solution, and it is important to keep this constant. The solution contains some clay as a suspension, some tallow as an emulsion and some inorganic salts as a solution, as well as gelatinized starch and gums as a colloidal suspension. At present, an attempt is being made to develop a machine which will apply a fixed weight of solids to the thread, even if the viscosity of the solution should vary.

In the first paper of the afternoon session, on "The Mixing of Wheaten Flour Doughs", Mr. S. J. Cornford (British Baking Industries Research Association) reviewed the literature on this subject and considered how the mixing characteristics of flour doughs can be used to predict the suitability of a flour for bread-making. The effect of mixing on flour doughs depends partly on the atmosphere in which the mixing is carried out, as the mechanical effect is modified by air inclusion and oxidation during mixing. Three factors contribute to the resistance encountered during mixing: mechanical resistance, protein swelling and sticking. The peaks in the mixing curve due to these causes do not necessarily coincide, and it is possible for some agents to affect one peak without affecting the others.

A paper by Mr. D. C. Broome (Limmer and Trinidad Lake Asphalt Co.) was read in his absence by Mr. A. E. Howes. Although mixing of thick materials is such an important technical matter to the asphalt industry, there has been little improvement in its mixing machines during the past half-century. Some progress is now being made, and a continuous mixer for bituminous road-mixes has been introduced in the United States. In Britain an improved type of 'whirlpool mixer' has recently been developed, and this enables mixing to be carried out in a considerably shorter time than with the older types of mixer. An 'impactor' type of mixer has also been reported from Germany.

A paper from the Road Research Laboratory, West Drayton, submitted by Dr. A. R. Lee, was read in three parts by members of the Laboratory staff. Mr. K. E. Clare gave an account of the problems involved in mixing soil and cement when making special types of road. One of the main difficulties is segregation during *in situ* mixing due to the greater density of the cement, resulting in a low concentration of cement at the upper surface of the road.

Mr. F. N. Sparkes discussed the problems caused by the fact that engineers tend to specify concrete mixes which are 'leaner' than formerly. Such mixes

3–5 μ or less, they could be completely separated into two groups. One group has a Curie point between 500° and 530° C., and the other between 200° and 250° C. These two groups correspond with the *A*- and *B*-constituents, respectively. *AB*-grains which contain *A*- and *B*-constituents in a ratio of approximately 6 : 1 predominate.

As mentioned previously[3], both the *A*- and *B*-grains show normal thermo-remanent magnetization, and only the *AB*-type can give reverse thermo-remanent magnetization by cooling in a weak magnetic field. Even a single grain of *AB* can possess reverse thermo-remanent magnetization, whereas a mixture of the *A*- and *B*-grains does not show it. It is concluded, therefore, that a strong magnetic interaction among the *A*- and *B*-constituents which are contained in each single *AB*-grain alone is responsible for the appearance of reverse thermo-remanent magnetization.

Thus, Néel's two-phase theory[4] seems to be the preferred explanation of the reverse thermo-remanent magnetization of Haruna and Asio rocks, as long as we assume the effect of magnetic interaction of two constituents only within each single grain of composition *AB*. Assume now that the orientation of the magnetic domains of the *A*- and *B*-constituents are fixed along the effective magnetic field at T_A and T_B, respectively, where $T_A > T_B$. If we cool down the *AB*-grains from a temperature higher than T_A in a weak magnetic field H, the intensity of magnetization $J(T)$ at a temperature between T_A and T_B ($T_A > T > T_B$) will be given by:

$$J(T) = J_r(T) + J_i^A(T), \qquad (1)$$

where $J_r(T)$ denotes the magnetization reversible with respect to H, and $J_i^A(T)$ is the irreversible magnetization of the *A*-constituent, being represented by:

$$J_i^A(T) = n_A v_A \sigma_A(T), \qquad (2)$$

where n_A, v_A and $\sigma_A(T)$ are the number of domains in the *A*-constituents fixed at T_A, their mean volume and intensity of spontaneous magnetization, respectively. Obviously the direction of $J_i^A(T)$ as well as that of $J_r(T)$ will be parallel to the direction of H.

At T_B, where the *B*-constituent also becomes ferromagnetic, the effective magnetic field, $H_{\text{eff.}}$, for the *B*-constituent will be given by:

$$H_{\text{eff.}} = H - \{\alpha J_r(T_B) + \beta J_i^A(T_B) + \gamma J_i^B(T_B)\}, \qquad (3)$$

where α, β and γ denote coefficients representing the contributions of the three different kinds of magnetization to the demagnetizing field. They are subject to the shape of the boundaries of those three phases and their geometrical relation to one another. If $H_{\text{eff.}} < 0$ at $T = T_B$, the direction of $J_i^B(T_L)$ is opposite to that of H, and, consequently, to that of $J_i^A(T_B)$. Thus the irreversible magnetization $J_i(T)$ at temperatures below T_B will be represented by

$$J_i(T) = J_i^A(T) + J_i^B(T) = n_A v_A \sigma_A(T) - n_B v_B \sigma_B(T), \qquad (4)$$

where $T < T_B$ and n_B, v_B and $\sigma_B(T)$ are the quantities for the *B*-constituent corresponding to n_A, v_A and $\sigma_A(T)$ for the *A*-constituent.

Then, if

$$\frac{n_A v_A}{n_B v_B} < \frac{\sigma_B(T_0)}{\sigma_A(T_0)}, \quad (T_0 < T_B) \qquad (5)$$

at $T = T_0$, the remanent irreversible magnetization $J_i(T)$ at $T = T_0$ becomes reversed. Hence the necessary two conditions for getting reverse thermo-remanent magnetization at a comparatively low temperature T_0, say, atmospheric temperature, are given by equation (5) and $H_{\text{eff.}} < 0$ at $T = T_B$.

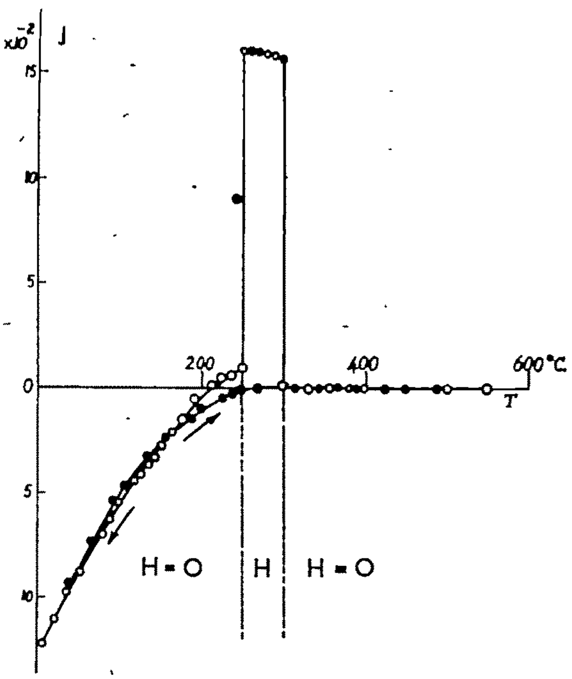


Fig 1. Development of reversed transverse remanent magnetization with decrease of temperature and its disappearance with increase of temperature. Magnetic field ($H = 0{\cdot}5$ Oe.) is applied only during evolving from 300° to 250° C. Haruna magnetic minerals

Since T_B is near the Curie point of the *B*-constituent, $\sigma_B(T_B) \lessdot \sigma_A(T_B)$, and since $n_B v_B \lesssim n_A v_A$ according to actual measurements, we get:

$$J_i^A(T_B) = n_A v_A \sigma_A(T_B) \gtrdot J_i^B(T_B) = n_B v_B \sigma_B(T_B). \qquad (6)$$

From equations (5) and (6) the necessary condition for reverse thermo-remanent magnetization at $T = T_0$ is expressed as:

$$\frac{\sigma_B(T_0) - \sigma_B(T_B)}{\sigma_A(T_0) - \sigma_A(T_B)} > \frac{n_A v_A}{n_B v_B}. \qquad (7)$$

In the case of the *AB*-grains of Haruna rock, $n_A v_A$ is about six times as large as $n_B v_B$. Hence the reversed thermo-remanent magnetization effect can be obtained in this case provided that $\sigma_B(T_0) - \sigma_B(T_B)$ exceeds six times $\sigma_A(T_0) - \sigma_A(T_B)$. As will be seen in Fig. 1, the temperature coefficient of σ_B is markedly larger than that of σ_A. Hence the condition given by equation (7) is fulfilled.

Fig. 2 illustrates an example of the development and decay of partial thermo-remanent magnetization with increase and decrease of temperature respectively. The magnetic field affecting the ferromagnetic mineral groups of the Haruna rocks in the cooling process from 600° C. is kept at zero down to 300° C., and at 0·5 Oe. from 300° C. to 250° C. A positive normal magnetization takes place within this range of temperature chiefly due to reversible magnetization. When the magnetic field is removed at 250° C., there remains a positive remanent magnetization, which decreases with decrease in temperature in the non-magnetic space, becoming reversed below about 200° C. Since the temperature coefficient of this reversed thermo-remanent magnetization is almost constant and large, it will be clear that it is chiefly due to the magnetization of the B-constituent[5]. The change of the reversed thermo-remanent magnetization with temperature in the furnace on reheating in a non-magnetic space is in fairly good agreement with that found in the cooling process, so long as the temperature does not exceed 200° C. It must be noticed that the reversed magnetization in this reheating process never takes a positive value. This fact may indicate that the reversible magnetization $J_r(T)$ in equation (3) takes an important role in giving a negative value of H_{eff}.

Table 2

Source	Grain	Crystal structure	Lattice constant
Haruna	A	Cubic (inverse spinel)	$a = 8{\cdot}403 \pm 0{\cdot}003$ A.
	B	Rhombohedral	$\left\{\begin{array}{l} a_{rh} = 5{\cdot}480 \pm 0{\cdot}002 \text{ A.} \\ \alpha = 55^\circ\ 08' \pm 1' \end{array}\right.$
	AB	$A + B$	$a = 8{\cdot}401$ A., $a_{rh} = 5{\cdot}473$ A
Asio	A	Cubic (inverse spinel)	$a = 8{\cdot}397 \pm 0{\cdot}004$ A.
	B	Rhombohedral	$\left\{\begin{array}{l} a_{rh} = 5{\cdot}483 \pm 0{\cdot}004 \text{ A.} \\ \alpha = 55^\circ\ 01' \pm 3' \end{array}\right.$
	AB	$A + B$	$a = 8{\cdot}40$ A., $a_{rh} = 5{\cdot}48$ A.
Magnetite		Cubic (inverse spinel)	$a = 8{\cdot}397 \pm 0{\cdot}003$ A.
Ilmenite		Rhombohedral	$\left\{\begin{array}{l} a_{rh} = 5{\cdot}540 \pm 0{\cdot}002 \text{ A.} \\ \alpha = 54^\circ\ 44' \pm 2' \end{array}\right.$

The problem of self-reversal of thermo-remanent magnetization can be reduced to the following two main points: What are the magnetic and crystal structures of the A- and B-constituents? And how have these two interacted with each other within the AB-grains? In order to investigate the first question, chemical and X-ray analyses were carried out. Results for the chemical analysis of Haruna rock are shown in Table 1.

Table 1

Constituent	For all grains	For A grains	For B grains
Fe_2O_3	57·9 per cent	58·7 per cent	43·5 per cent
FeO	34·7 ,,	34·2 ,,	24·2 ,,
TiO_2	7·4 ,,	7·0 ,,	32·3 ,,

All percentages are by weight

The chemical compositions of the A- and B-grains are plotted on the diagram of the ternary system of Fe_2O_3—FeO—TiO_2 in molecular percentages in Fig. 3. These results indicate that the A-constituent is a titanomagnetite the Curie point of which must be a little less than that of pure magnetite (575° C.), while the chemical composition of the B-constituent is nearly on the line connecting ilmenite and hæmatite.

The ratio of A to B in all the ferromagnetic minerals is estimated to be about 70 : 1 from the chemical analyses given in Table 1, and this value is nearly in accord with the results of the magnetic separation. On the other hand, the X-ray analysis of the A-, B- and AB-grains gave the results shown in Table 2, in which are shown the lattice constants of nearly stoichiometric magnetite and ilmenite for comparison.

The lattice constant and the crystal structure of the A-constituent are nearly the same as those of magnetite, while the crystal structure of the B-constituent is clearly rhombohedral, with the lattice parameters a little shifted away from those of pure ilmenite towards hæmatite. These results are, then, in good agreement with the chemical analyses.

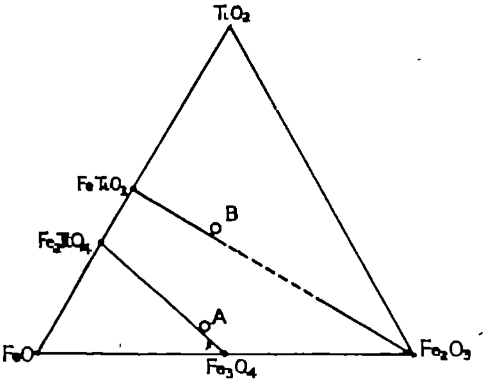

Fig. 3. Chemical composition of the A- and B-constituents of ferromagnetic minerals of Haruna rocks. Full lines show possible ranges of solid solution (after Pouillard, ref. 6)

The X-ray spectra of the AB-grains showed, both for Haruna and Asio rocks, just a superposition of those of the A- and B-constituents. Here again we have evidence that the AB-grain is a mixture of the A- and B-constituents.

One of the remaining difficulties is why the B-constituent, which has a rhombohedral structure close to that of ilmenite, is so strongly ferromagnetic. The saturation magnetization σ_B of this constituent increases linearly with decrease in temperature down to the temperature of boiling liquid air, according to our measurements. Néel[7] has also shown that σ_B increases almost linearly with decrease in temperature down to about 1° K. This result may suggest that the B-constituent is one of Néel's ferrimagnetics. The magnetic properties of the B-constituent seem to present a new problem in crystal physics.

So far as the majority of reversely magnetized rocks are concerned, the above mechanism of self-reversal of thermo-remanent magnetization may not be responsible for the phenomenon observed, because the presence of such a peculiar mineral as the B-constituent seems to be quite rare. According to our experiments, however, the ferromagnetic minerals in rocks very generally consist of various compositions of differing Curie points and they interact magnetically with each other. While the magnetization of some compositions is reversed, this reversed component is not as strong as in the Asio and Haruna rocks. If the magnetization of any normally magnetized part disappeared or was diminished due to some chemical or physical alteration during a long period of time, and the reversed part were comparatively stable, the resultant magnetization might be reversed. Therefore, one cannot yet abandon as an alternative the possibility of some form of self-reversal in rock magnetism generally. Experimental examination of reversely magnetized rocks with this as a working hypothesis is now proceeding.

The experimental investigations mentioned in this article have been carried out with S. Akimoto and S. Uyeda and with the co-operation of Prof. L. Néel. My thanks are due to Profs. P. M. S. Blackett and E. Thellier, Drs. J. A. Clegg and H. Manley, Mr. J. Hospers and others for valuable discussions.

Radio-Frequency Radiation from the Spiral Nebula Messier 81

FOLLOWING the detection[1] of radio-frequency radiation from the Great Nebula in Andromeda *M*.31, the 218-ft. paraboloid at the Jodrell Bank Experimental Station has been used for continuing the observations of extra-galactic nebulæ, and the preliminary results have already been published[2]. The survey has recently been extended to the region of sky around the bright *Sb*-type spiral nebula *M*.81, which is of particular interest since a previous survey[3] failed to detect the radiation from this nebula, which is one of the brightest in the sky, although in the same survey fainter nebulæ were observed. Fig. 1 is a record of the power received with the aerial beam directed to declination N. 69°, and shows a radio source superimposed on a gradient of the background radiation. The co-ordinates and intensity of this source, together with those of the nebula, are given in Table 1, and in view of the close agreement of the co-ordinates, the source may be provisionally identified with the nebula.

As the source is so clearly resolved, and as its apparent angular diameter is small compared with the width of the aerial beam (2° between half-power points), the observation probably represents the most reliable measurement at present available of the intensity of the radiation from a late-type spiral nebula.

The measurement of the radio intensity from *M*.81 has been combined with the previous observations[2,5] to determine the ratio between the radio flux and light flux for individual nebulæ. A previous suggestion that the apparent photographic magnitude increases more rapidly than the apparent radio magnitude was largely based on the value of intensity for a faint nebula ($M_{pg} = +16 \cdot 0$) which was derived from a cluster in Perseus. However, it has since been pointed out by Minkowski (private communication) that the Perseus cluster contains a peculiar nebula *NGC* 1275 which apparently consists of two nebulæ in collision. This object may be an abnormal radio emitter, and therefore its inclusion in the analysis was invalid. The present result, together with the previous results[5] on individual nebulæ, are consistent with a constant ratio between the total light flux and radio flux from late-type spiral nebulæ, and show that the intensity from a nebula of apparent magnitude + 10 (Shapley–Ames) is approximately $4 \cdot 2 \times 10^{-26}$ watts/sq. m./c.p.s. at 158·5 Mc./s. The variations which have been observed in the difference between the apparent radio and photographic magnitudes are of the order of 0·5 magnitude, and are probably due either to the effects of visual obscuration corresponding to the varying galactic latitudes and orientations of the nebulæ, or (as in the case of *M*.31) to errors in the integration of the observed flux over the nebulæ.

The Typical Perseid Meteor Spectrum

THE first Perseid meteor spectrum was photographed by S. Blajko at Moscow on a blue-sensitive plate on August 12, 1904[1,2]; but up to 1934 only two additional examples of such photographs had been secured. The emission lines of Fe I, Ca I, Ca II, Mg I, Mn I and Al I were identified in the early photographic spectra, the *H* and *K* lines of Ca II generally being the strongest feature.

In various programmes of meteor photography I have carried out at the David Dunlap Observatory and at the Dominion Observatory in the period 1934–53, some twenty-five Perseid spectra have been secured. Faint records on panchromatic plates were first obtained in 1934[3], and the lines of Na I in the yellow and Si II in the red were tentatively identified. This identification was confirmed by better spectra secured in 1939 and 1940[4]. More recently, through the use of replica transmission gratings, spectra showing considerably better resolution in the red have been photographed at the Dominion Observatory[5]. In particular, spectrum No. 126, obtained on August 12, 1952, showed a detail of more than a hundred bright lines. Lines of hydrogen and of Fe II, which had been suspected in earlier spectra, were definitely identified in this meteor. In the 1950 observations two faint spectra were

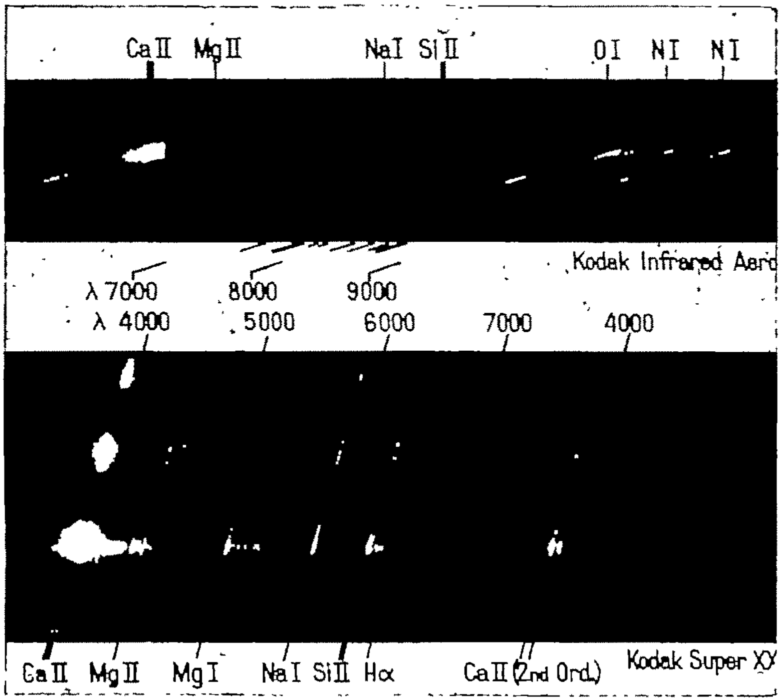

Fig. 1. Perseid meteor spectra, photographed at the Dominion Observatory, Ottawa, in August 1953

photographed on Kodak Aero Infra-red emulsion and the O I lines at 7774 A. were found. An infra-red spectrum with considerably more detail was photographed at Ottawa on August 14, 1953, and the brightest lines in the range 7000–9000 A. have been satisfactorily identified as due to O I and N I, confirming all the faint features in the 1950 infra-red spectra. The 1953 infra-red spectrum is reproduced herewith.

As noted some years ago[4], all Perseid spectra are remarkably similar and seem to show the same general features within the limitations of photographic resolution and emulsion sensitivity. In the accompanying table the multiplets that have been identified in Perseid spectra are listed, the numbers in brackets corresponding to those used in Dr. C. E. Moore's multiplet table[7]. Doubtful identifications have been omitted. The table contains seventy-two multiplets of ten neutral atoms and four ionized atoms. These multiplets may be considered a normal feature of the light of bright Perseid meteors in the wave-length range 3500–9000 A.

MULTIPLETS IN PERSEID METEOR SPECTRA

H	(1)
N I	(1) (2) (3) (16) (20) (25)
O I	(1) (4)
Na I	(1) (5) (6)
Mg I	(1) (2) (3) (9) (11) (14)
Mg I	(23)
Mg II	(4)
Al I	(1) (5)
Si I	(2) (3) (9) (10) (11) (16)
Si II	(1) (2) (3) (4) (5)
Ca I	(1) (2)
Ca I	(3) (4) (18) (19) (20) (21) (23) (47) (49)
Ca II	(1) (2)
Mn I	(2)
Fe I	(1) (2) (3) (4) (5) (15) (16)
Fe I	(20) (21) (23) (41) (42) (43) (152) (168) (268) (318)
Fe II	(27) (28) (37) (38) (42) (48) (49) (74)

The Hα line appears quite definitely and is of moderate strength. Its presence seems to lend support to Whipple's comet model[8], which suggests large quantities of hydrogen ices in the original particles making up a comet nucleus. Some of these hydrogen ices might well be retained in meteoritic particles large enough to produce a Perseid fireball in the visual magnitude range covered by these spectra, namely, – 2 to – 7. (*Note added in proof*. Dr. G. P. Kuiper has suggested to me the additional possibility of the hydrogen occurring in the water of crystallization of certain compounds possibly present in cometary meteoroids.)

Two spectra photographed in 1952 with a rotating shutter show good detail in the light of the train immediately behind the meteor, termed either the evanescent train or wake. The chief feature of this light is the complete absence of all ionized atoms except Ca II, and the relatively greater strength of the multiplets Fe I (1), (2), (3), Mg I (1) and Ca I (1). In one case there is clear evidence that this trailing luminosity was produced by a small portion that broke off from the main mass, and luminous dust at a lower excitation than the meteor head may be a common feature in the wake of fast fireballs. The train spectra photographed in 1952 show the lines of Ca II, in contrast to the train of the 1949 meteor[9] in which they were absent.

Geomagnetic Activity and the Sunspot Cycle

IT is well known that the daily international magnetic character figure C_i constitutes a valuable index for classifying days according to their magnetic activity averaged over a large part of the earth. As a measure of the intensity of geomagnetic disturbance, C_i is in fact comparable to the Zurich relative sunspot number S, which is a recognized measure of solar activity. Daily C_i values are available in an unbroken sequence from 1884 onwards.

In the course of a recent study of solar prominences recorded at Kodaikanal during the period 1905–50, the daily C_i figures for this period were analysed year by year into four groups: 0–0·4; 0·5–0·9; 1·0–1·4; and 1·5–2·0. These four groups may be conveniently designated as magnetically calm (D_1), slightly disturbed (D_2), moderately disturbed (D_3) and highly disturbed (D_4) days. To study the behaviour of geomagnetic activity during the last four sunspot maximum epochs, with their peaks in 1947, 1937, 1928 and 1917, a period of five years centred around each of these peaks was taken and the total number of days (1,826) in this interval was classified into the four groups D_1 to D_4. As a measure of sunspot activity (S) for the corresponding periods, the Zurich relative sunspot numbers for the individual years were summed. As a measure of prominence activity (P) for the periods the mean daily profile areas of limb prominences were similarly summed. The results are as follow:

Epoch	D_1	D_2	D_3	D_4	S	P
1945–47–49	755	637	321	113	549·6	21,816
1935–37–39	671	594	374	187	429·3	31,389
1926–28–30	716	582	371	157	311·4	30,178
1915–17–19	672	592	428	134	350·0	22,079

It is at once seen that, judged both by the number of highly disturbed and least disturbed days, the latest sunspot maximum epoch has been geomagnetically the least active. However, it is well known that spot activity during this cycle has been one of the highest on record. We also see that the previous cycle with its maximum in 1937 was geomagnetically the most active among the last four solar cycles. Comparison of the figures under D_4 and S shows that the frequency of magnetically highly disturbed days does not run parallel to sunspot activity. However, comparison of the figures under D_4 and P indicates a parallelism. High prominence activity is also associated with high geomagnetic activity. (In this connexion it should be mentioned that the P figure for 1915–19 is not quite comparable with the figures for the remaining epochs. The prominence data prior to 1922 are based on observations made at Kodaikanal only, whereas after that year the Mt. Wilson and Meudon Observatories have been co-operating with Kodaikanal by supplying copies of their photographs for the days on which observations were not possible at this station.)

The fact that prominence activity during the latest solar cycle has been less compared with the two previous cycles has been pointed out in a previous communication[1]. It is worth recalling that Behr and Siedentopf[2] and Kleczek[3] have found from their analyses of solar flare data that flare activity has also been less during the latest solar cycle as compared with the previous cycle.

Radio Noise-bursts from Solar *M*-Regions

In 1932, Bartels put forward the hypothesis that moderate geomagnetic storms with gradual commencements were associated with certain active regions on the sun which he called *M*-regions. Solar and geomagnetic studies in later years have confirmed the existence of these magnetically effective areas; but their exact nature still remains obscure. Some authors consider them to be regions from which sunspots have just disappeared, leaving behind a certain amount of activity; others regard them as long-lived dark filaments emitting slow corpuscles and closely connected with bright coronal patches.

Our knowledge about the origin of the more intense geomagnetic storms, on the other hand, is more certain. These are characterized by sudden commencements and show very close correlation with solar flares, which occur in the neighbourhood of spot-groups. Observational results of recent years have provided satisfactory evidence of the emission of both corpuscular and electromagnetic wave radiations from intense solar flares; the geomagnetic storm associated with a flare is due to the corpuscles and commences about one to two days after the optical observation of the flare, and the ultra-violet component of the wave radiation produces, in favourable circumstances, a 'crochet' in the magnetic traces synchronously with the flare, while the long-wave component in the radio-frequency region appears as a noise-burst almost synchronously with the flare. But, to our knowledge, no observational evidence has so far been published indicating that *M*-regions also can produce crochet-like disturbances in geomagnetic records and simultaneously emit radio waves similar to the noise-bursts from flares. The evidence provided by our recent observations in this regard is therefore of interest.

From the recurrence tendency of certain moderate magnetic storms investigated recently in this Observatory by B. N. Bhargava and A. M. Naqvi (this work is concerned with the study of the equinoctial increase in geomagnetic activity and will be published elsewhere), we were aware that an *M*-region would be traversing the disk between about August 18 and 31, 1953. Indeed, on the basis of this knowledge, this Observatory had issued a forecast of ionospheric and geomagnetic disturbances which proved to be successful. The predicted magnetic disturbances actually began on August 23 and ended by September 1. While the magnetic disturbances were in progress, the traces of all our *H*-magnetographs (Watson, La Cour and Askania) showed on August 24 and 25 two short-duration disturbances synchronously with two noise-bursts recorded by our 100-Mc./s. radio telescope. The same phenomenon occurred again on August 29. We reproduce in Fig. 1 the magnetic and solar noise records for the relevant periods. It will be noticed that the crochet-like disturbance in each case shows fluctuations identical in character to the variations of intensity in the noise-burst. Evidently this transient magnetic disturbance was caused by ultra-violet radiation emitted by the *M*-region, but it was not exactly like the usual crochet; nor was there any associated radio fade-out so far as could be judged from our ionospheric records, which are taken at 15-min. intervals. The close correspondence between the characters of the short-duration magnetic disturbance and the noise-burst seems to suggest a phase relationship between the intensity of ultra-violet emission and the intensity of radio-frequency radiation. It is tempting to infer from this that the ultra-violet radiation pressure was directly responsible for the variations in the acceleration of charged particles, giving rise to the radio-frequency emission.

It seems significant that throughout the period August 24–29 the spectroheliograms of this observatory showed that the visible disk was remarkably free from disturbances. There were no spots or calcium or hydrogen flocculi visible during this period, except for a very small flocculus visible on both K and H_α disk spectroheliograms very close to the east limb on August 29. On the hydrogen disk spectroheliograms there were only two or three very

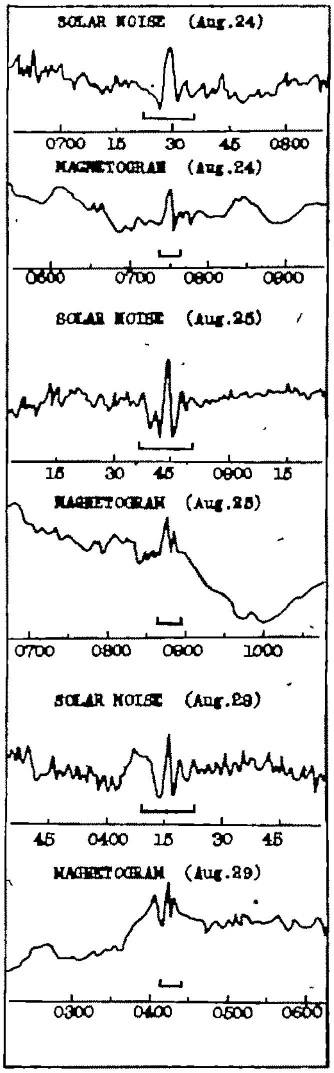

Fig. 1. Solar noise records and magnetograms (times in U.T.)

small and insignificant-looking absorption markings, which showed no activity as observed with the spectrohelioscope during the period in question; nor could they be identified as recurrent filaments during the previous transits of the *M*-region. The emission of ultra-violet radiation from the *M*-region could not, therefore, be attributed to any associated calcium or hydrogen flocculus in the manner suggested by Wulf and Nicholson[1]; although the three instances here cited demonstrate that emission of ultra-violet radiation does take place, at least in spurts, from an *M*-region. Neither does it seem possible to identify this *M*-region with any long-lived filament emitting slow corpuscular radiation, as suggested by Kiepenheuer[2].

We have examined our past magnetic and solar noise records for several months during which this particular *M*-region had been effectively causing recurrent magnetic disturbances. Although we think that there are indications of similar magnetic and noise phenomena during the previous transits of this *M*-region, the three instances here reported are by far the clearest and most striking. But from the examination of our past records, we feel convinced that the passage of *M*-regions is characterized by a notable increase in the short-term variability of noise intensity on 3-metre wave-length as compared with the quiet sun. Further observations are much to be desired, especially during the present minimum phase of the solar cycle.

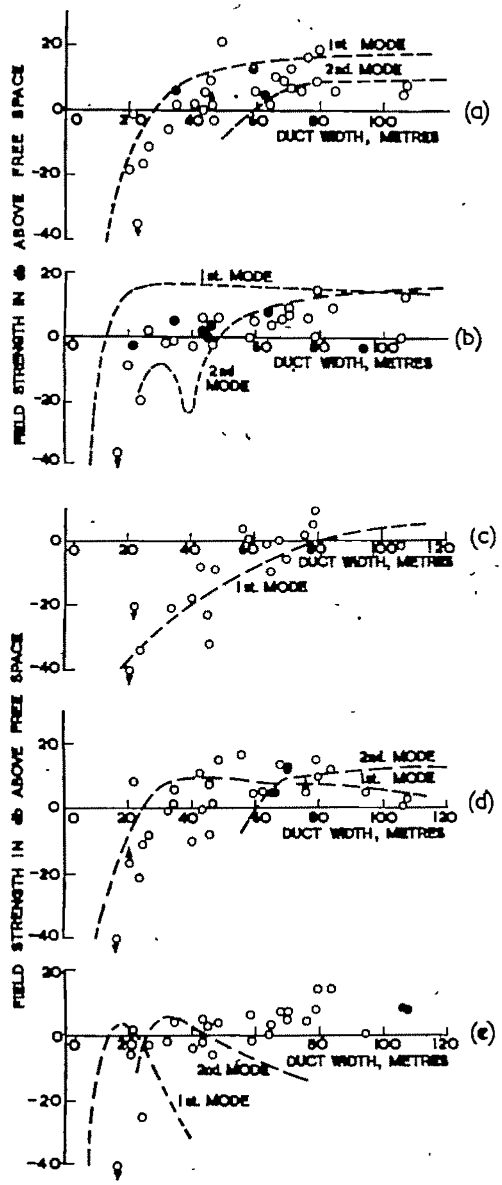
Ultra-short-wave Field-strength in a Ground-based Radio Duct

ALTHOUGH powerful methods have been developed for calculating the field-strength beyond the horizon of a transmitter for various profiles of atmospheric refractive index[1-3], the success achieved in their practical application has been somewhat limited[3,4]. The chief reason for this is that the refractive-index profile usually varies considerably along the transmission path, especially in coastal regions[5], and in this case the calculation of the full solution, if more than one propagation mode has to be taken into account, becomes prohibitively complex[6]. It is useful, therefore, to seek an empirical relationship between the field-strength and the characteristics of the refractive-index profile averaged by some means along the transmission path. Suitable experimental data have recently become available in a report published by the New Zealand Government[7], which contains a large number of field-strength observations made at various heights over the sea under widely differing super-refractive conditions. It can be shown[1] that the width of the radio duct is the most important single parameter in determining the field-strength beyond the horizon of a transmitter, and we therefore confine our attention to the duct width in the following discussion. Ground-based ducts only are considered.

The New Zealand field-strength observations were made at wave-lengths of 3, 9 and 60 cm., in ducts from about 15 to 100 m. in width, at ranges between about 20 and 200 km. from the fixed terminals at the coast. The transmission path was divided into 20-km. intervals, centred at 20 km., 40 km., etc., up to 200 km. from the fixed terminals, and the average duct width out to each of these ranges was determined from the smoothed refractive-index data as given in the report. The maximum value of the field-strength in the region of the duct was then determined from the records. At 3 and 9 cm., the height of the maximum usually lay between 10 and 30 m. from the sea surface, and at 60 cm. between 30 and 60 m. Where the field-strength/height curves showed no local maximum in the region of the duct (that is, when the lowest propagation mode was very leaky), the value at the top of the duct was taken.

The maximum field-strength values plotted against the average duct width are shown in the diagram for the 20-km. range-interval centred at 100 km. from the fixed terminals. As the duct width increases from zero, the field-strength generally increases from a low value up to a certain level, beyond which it remains almost constant or tends to increase only slowly with further increase in duct width. Such a relationship would be expected from theory[1], the change occurring at the duct width where the first mode goes from a leaky to a trapped state, referred to here as the 'critical' duct width. Owing to the



Maximum field-strength in duct at 100 km. as a function of duct width.

♀♂, Field-strength less than (greater than) indicated by < 10 db.; – – –, theoretical value of maximum field-strength in duct for one-half power law refractive index profile.

(a) Wave-length, 9 cm.
(b) Wave-length, 3 cm. } terminal height, 8 m.
(c) Wave-length, 60 cm.
(d) Wave-length, 9 cm. } terminal height, 26 m.
(e) Wave-length, 3 cm.

amount of scatter, the critical value cannot be determined with precision from the plots; it appears o be about 27 m. at 3 cm. wave-length, 45 m. at 9 cm., and nearly 90 m. at 60 cm. wave-length. The catter is generally much greater for duct widths less han critical than for wider ducts. For all plots the mount of scatter at each wave-length tends to ncrease with range. This is to be expected from the method of calculating the duct width[6].

An interesting feature brought out by the analysis s that the field-strengths at 9-cm. wave-length for uct widths greater than critical are, on the average, reater than the corresponding values at 3 cm. between the range of 50 and 100 km., the average factor is 3·8 db., while between 150 and 200 km. it is 5·1 db. These figures imply also that the horizontal attenuation is greater at the 3-cm. wave-length than at the 9-cm. The attenuations for duct widths greater than critical are shown in the table.

Range interval	Average horizontal attenuation (db./km.)		
	9-cm. wave-length	3-cm. wave-length	Theoretical value for a trapped mode
50–100 km.	0·09	0·16	0·06
150–200 km.	0·05	0·08	0·025

The significantly greater attenuation at 3 cm. is probably due to the greater amount of scattering from the sea surface at the shorter wave-length. This conclusion is similar to that reached by Pekeris[4] in analysing the results of experiments made in the Caribbean Sea in 1945[8].

An empirical formula for determining the maximum field-strength in the duct as a function of duct width would be of little use for ranges beyond 100 km. from the transmitter, owing to the amount of scatter in the results. At less than 100 km. the scatter is only moderate at all three frequencies, at least for duct widths greater than critical; but it is doubtful if any empirical formula would be much better than one based on simple mode-theory for a horizontally stratified atmosphere with the duct width equal to the average value. This is shown by comparing the experimental points in the figure with the theoretical curves calculated from Booker and Walkinshaw's formula[1] for a one-half power law profile of modified refractive index. At 3-cm. wave-length the term in this formula depending on the fixed height of the ground terminal has an undue influence on the shape of the curves; much better agreement with the experimental values could be obtained by making reasonable assumptions about the contribution due to this term, and allowing for the extra horizontal attenuation at this wave-length.

It appears, therefore, that if the average width of a ground-based duct can be predicted from meteorological data to be greater than the critical value for some particular wave-length, a useful, though rough, estimate of the maximum field-strength in the duct can be made at centimetre and decimetre wave-lengths, at least up to ranges of 100 km. from the transmitter.

Application of a New Adsorption Method in the Study of Flow of Fluids

In a paper entitled "Adsorption under Fixed Hydrodynamic Conditions, I"[1], we have expressed the opinion that under our conditions adsorption can be used for the investigation of the flow of liquid fluids. The object to be examined is coated with a thin layer of silica gel by spraying it with a suspension of finely powdered silica gel in an acetone solution of cellulose nitrate. If an object thus prepared is placed in a stream of a dilute aqueous solution of methylene blue (0·00015 per cent) and allowed to stand for 5–20 min., on the white surfaces of the object there will appear uneven blue colorations or 'adsorption spectra'. We think that the differences in intensity of coloration, that is, the differences in the amounts of the adsorbed colour, are the consequence of different thicknesses of the boundary layers in the stream of fluid above the boundary surface. Since, in order to reach the surface of the adsorbent, the coloured substance should diffuse through one part of the boundary layer, therefore, the thinner the boundary layer the greater the amount of the coloured matter which will diffuse in the same period of time.

We have obtained results (unpublished) confirming this and showing that the intensity of coloration of the surface area of the adsorbent depends on the rate of flow of the fluid, and that the greater the rate of flow the greater the intensity of coloration at the surface of the adsorbent; at the same time, the intensity of coloration is greatest on smooth surfaces in places where the solution first reaches the surface, and it gradually decreases along the surface. This leads to the conclusion that the thickness of the boundary layer decreases with the rate of flow and increases with the distance which the fluid flows. This is in complete agreement with the theoretical suppositions. It means that above intensely coloured places on the object the boundary layer is relatively thin, due to high speeds, or to the direction of flow being at right angles to the boundary surface. Faintly coloured places, according to our view, indicate low rates of flow of the solution, slight whirls, places from which the boundary layer diverges, or places where there is no flow or currents of opposite directions are meeting, thus producing 'dead' zones.

Such 'adsorption spectra' have been produced on aluminium plates (137 mm. × 25 mm. × 1·1 mm.) to which were fastened the objects the effects of which on the rate of flow we wished to examine. The objects were coated with silica gel as described earlier, and placed in a long straight tube (diameter 26·0 mm.) through which, for a period of 5 min., a solution of methylene blue was allowed to flow at a given rate.

In one experiment, with a vertical cylinder (diameter 12 mm., height 14 mm.) and at a velocity of 0·44 m./sec., various semicircular, rather faintly coloured concentric surfaces appear, pointing to the 'dead' zones caused by the meeting of whirls in front of the object. On the front surface of the cylinder, as well as at its sides, faintly coloured places are seen which are the consequences of the diversion of the boundary layer from the cylinder. The faintly coloured places behind the cylinder are the consequences of relatively slow movements of slight whirls, whereas on the sides of the cylinder the intensely coloured areas due to streaming at high rate of flow are shown. When a diffusor is introduced into a stream of velocity 0·35 m./sec., it is characterized by a narrow band or dead zone at the entrance to the diffusor, due to the collision of opposed fluid streams with the narrow surfaces of the diffusor. Another characteristic is the non-homogeneity of the flow of the fluid shown by the adsorption spectrum in front of the entrance to the diffusor and its homogeneity at the exit.

We believe that this adsorption method of studying flow has several new and useful characteristics: it gives permanent records—'adsorption spectra'—even of the most complex flows along the actual surface without the aid of photographic or other measuring instruments; it is simple; it can be used for large surfaces; and it can also record 'micro flows' which are difficult to observe by other methods. We believe that the method, supplemented by colorimetric measurement of intensity, indicates a means of passing from qualitative to quantitative demonstrations of flow.

A Relativistic Treatment of Rigid Motion

In the following we shall set up Lorentz-invariant equations for the rigid motion of pairs of points and then inquire into the way special relativity modifies the classical kinematical properties of rigid bodies.

Starting from the principles used by M. Born[1] in arriving at the conditions of rigid motions of continua, we shall consider the motion of the point $P_2[\mathbf{r}_2 = \mathbf{r}_2(t)]$ rigid in relation to the point $P_1[\mathbf{r}_1 = \mathbf{r}_1(t)]$, whenever the s_{12} world distance drawn perpendicularly to the world line of P_1 from any point $\mathbf{r}_2(t_2)$ of t_2 time of the world line of P_2 appears to be constant:

$$\frac{d\mathbf{r}_1(t_1)}{d\tau_1}[\mathbf{r}_1(t_1) - \mathbf{r}_2(t_2)] - c^2\frac{dt_1}{d\tau_1}[t_1 - t_2] = 0, \quad (1)$$

$$[\mathbf{r}_1(t_1) - \mathbf{r}_2(t_2)]^2 - c^2[t_1 - t_2]^2 = s_{12}^2. \quad (2)$$

In this system of Lorentz-invariant equations, τ_1 is the proper-time of the point P_1 at the value $t_1 = t_1(t_2)$ of the system-time, in which the condition (1) of orthogonality has just been satisfied.

The function $t_1 = t_1(t_2)$, that is, equation (1) determining the time t_1 to be considered later 'conjugated' to t_2, may be written, provided the condition $\dot{\mathbf{r}}_1^2 < c^2$ is satisfied, also in the following form:

$$\frac{d\mathbf{r}_1(t_1)}{dt_1}[\mathbf{r}_1(t_1) - \mathbf{r}_2(t_2)] - c^2[t_1 - t_2] = 0. \quad (3$$

Owing to the function $\mathbf{r}_j = \mathbf{r}_j(t)$ $[j = 1,2]$ being of single value, the derivative $dt_2/dt_1 > 0$. By differentiating equation (2) with respect to t_1 we may set up also symmetrical conditions instead of (1, 2), which appear to be asymmetrical in j. We may then write, on considering (3):

$$\frac{d\mathbf{r}_2(t_2)}{dt_2}\,[\mathbf{r}_2(t_2) - \mathbf{r}_1(t_1)\,] - c^2[t_2 - t_1] = 0. \qquad (4)$$

Unlike equations (1, 2), equations (3, 4) are symmetrical with respect to j. For this reason the rigidity of P_1 as regards P_2, as well as the correlation of their system-times, are reciprocal. The postulate of rigidity as put forward in the foregoing may be expressed also by equations (2, 3).

If $\mathbf{r}_j = 0$ holds good at one, at least, of the points, then $t_1 = t_2$ and, consequently, s_{12} appearing in equation (2) must necessarily always mean the (invariant, intrinsic) spatial distance of the pair of points.

From equations (2) and (3), the following statements can be made:

(1) A rigid pair of points moving in its own direction with constant velocity shows Lorentz–Fitzgerald contraction.

(2) On a line at rest two points with accelerations identical and constant in time do not move rigidly. In consequence, the theory of relativity does not, in any of its aspects, allow the construction of a rigid system of co-ordinates of constant acceleration.

(3) In an inertial system, a rigid plate rotating with constant angular velocity is definable, but on its plane the intrinsic metric is non-Euclidean, and this meets correctly the calculations made by C. W. Berenda[2] and N. Rosen[3].

(4) A rigid pair of points has five degrees of freedom, provided that $s_{12} \neq 0$.

(5) If P_1P_2, P_2P_3 and P_3P_1 are rigid pairs of points (a 'rigid triangle') and $(s_{12} \pm s_{23})^2 \neq s_{13}^2$, this rigid triangle then has six degrees of freedom.

(6) If, however, $(s_{12} \pm s_{23})^2 = s_{13}^2$, that is, the three points lie on a rigidly moving straight line (the triangle having degenerated to a straight line), the orbit of P_3 may be calculated from the orbits of P_1 and P_2:

$$\begin{aligned} t_3 &= t_1 \pm (t_1 - t_2)\, s_{13}/s_{12}, \\ \mathbf{r}_3(t_3) &= \mathbf{r}_1(t_1) \pm [\mathbf{r}_1(t_1) - \mathbf{r}_2(t_2)\,]\, s_{13}/s_{12}. \end{aligned} \qquad (5)$$

(7) A rigid triangle may be fixed permanently in an inertial system.

(8) The orbit of a point rigid in relation to all the three points of a rigid triangle not degenerating to a straight line is determined by the orbits of the three points (the case of a 'rigid tetrahedron').

(9) If there exists a value of the system-time at which all three points of the base of a tetrahedron are at rest in an inertial system, the vertex of this tetrahedron will, at the same value of the system-time, be at rest as well.

(10) The vertices not common of two rigid tetrahedrons ('bitetrahedron') possessing a common base can, in general, not be rigid relative to each other.

It follows from (7), (8) and (9) that the vertices of rigid bitetrahedrons may be permanently stopped in an inertial system and, by this, we may map all the five vertices of the bitetrahedron on a fixed congruent bitetrahedron in Euclidean space. If all the ten combinations of the five points of a rigidly moving bitetrahedron were rigid, the same relation determining the metric would then exist, even during motion, between the ten invariant space-distances s_{jk} constant in time, as with that of a fixed congruent bitetrahedron placed in Euclidean space. We have, however, found in the foregoing that there may exist also a non-Euclidean metric with rigidly moving bodies. Consequently, not all the ten pairs of points can necessarily be rigid.

We may, therefore, state that a system of more than four points, moving rigidly, in all possible combinations is, in general, undefinable[4]. The definition of such a system would demand the abandonment of three of six degrees of freedom, a view already put forward by G. Herglotz[5].

A Simple Formulation of the Unquantized Laws of Electrodynamics

As a preliminary to quantization, it is desirable to have the laws of classical, relativistic electrodynamics in their simplest possible form. The following formulation of the laws governing the flow of a continuous distribution of electricity is offered.

If there is no interpenetration of streams, the fluid is fully described by its time-like, divergence-free current-density 4-vector **J**, the 'flow vector' for short. The 4-velocity **U** is along **J** and is of unit interval: $\mathbf{J} = N\mathbf{U}$, where N is the charge density measured in the local rest-frame. It is usual to absorb the sign of the charge in N and to let **U** be a 'future' vector always; but our formulation is simplified by keeping N positive and letting **U** take up the sign of the charge so that it becomes a 'past' vector where the fluid is negative. The three ratios of the space-components to the time-component still give the correctly orientated non-relativistic 3-vector of velocity.

Accepting direct action between streams one would, intuitively, expect manifestations of **J** only at zero-interval points in the future. Hence an intuitively effective flow-vector **A** results from **J** by weighting with the delta-function that singles out the light-cone and integrating over the entire past:

$$\mathbf{A}(\mathbf{r}) = 2\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\int_{-\infty}^{t} \mathbf{J}(\mathbf{r}')\,\delta\left((\mathbf{r}-\mathbf{r}')^2\right) dx'\,dy'\,dz'\,dt'.$$

With the factor 2, the effective flow vector **A** becomes exactly the 4-vector of the retarded potentials.

The effect caused by **A** is that of directing **J**, that is, determining **U**; for with mc^2/e as unit of potential (the mass/charge ratio of the fluid is assumed constant in magnitude) and the agreed sign convention, we obtain this convincingly concise statement of the Maxwell–Lorentz laws: "The sum of the local normalized flow-vector, **U**, and the locally effective flow-vector, **A**, maintains constant circulation". This follows from the equations of motion[1], but can be shown also to be a sufficient condition for the equations of motion to hold. The field concept is eliminated and any vacuum gaps are looked after automatically in the definition of **A**. Co-existing positive and negative streams with m/e ratios of the same magnitude are covered by the same law, without change of sign. With interpenetration, J is multi-valued, but A, the total over all streams, is not. The law holds separately for each stream.

Superconductivity[2] would make one suspect that where quantum effects are important, U + A is altogether irrotational and that large-scale vorticity arises only because multiply-connected charge configurations occur: in these an irrotational U + A can have circulation (fluxoid[2]) of integral strength in units *hc/e* around non-contractible paths. One could go further, lay down the quantization of vortices as a fundamental law and thus revive the Bohr–Sommerfeld theory in an invariant manner. Some recent calculations have strengthened a conjecture that the free electron represents the continuous charge distribution around one or two elementary vortices.

A Comparison of Lead Isotope Analysis Techniques

THIS communication reports the results of measurements of the relative abundances of the lead isotopes in a sample of lead analysed with the mass spectrometer at the Department of Physics, University of Toronto, Canada, and an instrument at the Atomic Energy Establishment, Harwell, England.

The purpose of this investigation was to compare isotopic lead analyses made using different techniques and different mass spectrometers. The results are of considerable importance in connexion with the methods of geological age determination based on the isotopic constitution of both radiogenic and ore leads.

The Toronto mass spectrometer was a 180°-instrument utilizing a Nier-type source. The sample in the form of lead tetramethyl was introduced through a capillary leak, and ions were produced by bombardment with a beam of 75-volt electrons. Full details of this technique have been published elsewhere[1].

The Harwell instrument was a 60° Nier-type spectrometer; the source arrangement consisted of a normal Nier-type gas source with a small furnace incorporated for distilling the material in the form of lead chloride or lead iodide into the ionization chamber. Magnetic scanning was utilized with both spectrometers.

The accompanying table gives the results of the analyses; several separate runs using fresh quantities of sample were made with each instrument.

The agreement of the Toronto and Harwell results suggests that isotopic analyses made using lead tetramethyl agree well with those involving the use of solid lead compounds as sources of ions. The effects of mass discrimination appear to be negligible, although a slight discrepancy in the abundances of lead-204 remains to be resolved. The results also serve to indicate the general reproducibility of lead isotope analyses.

We wish to thank Dr. L. R. Stieff, of the United States Geological Survey, for supplying the original samples of pure lead. Portions of this sample have also been supplied to other laboratories in the United States engaged in lead isotope work, and the results of their analyses will be published in the future so that all lead isotope studies will be strictly comparable.

Colour Bands in Fluorspar

IT has been shown in previous publications[1] that at least some of the maxima in the absorption spectra of natural coloured fluorites coincide with those obtained by artificial irradiation, thus completing the proof that the natural colour is due chiefly to radioactivity. Different fluorites show, however, very different colours and absorption spectra. This might be due in part to the fact that the conditions of formation of these minerals may vary greatly. It seemed, therefore, to be of interest to study the bands of different colour which are frequently seen in the same sample of fluorite, in which case the conditions of formation cannot have varied so much.

With a translucent piece of fluorite from Pe-shan, Che-Chian Province, China, a gift from Prof. Iimori, Tokyo, green with purple stripes, H. Adler, in the II Physics Institute, University of Vienna, was able to measure the absorption spectra of the green and

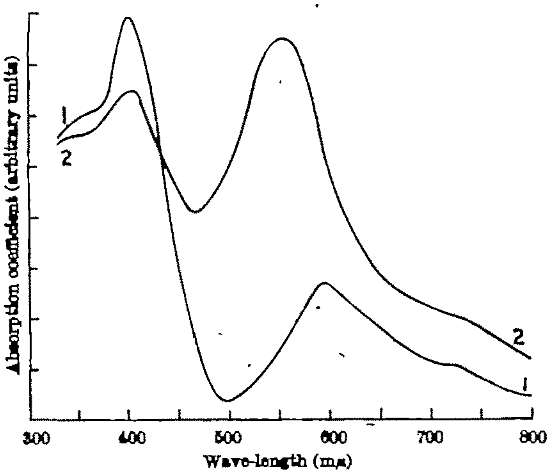

Fig. 1. Absorption spectra of the green (1) and violet (2) bands in fluorite from Pe-shan (China). Measurements from 10 to 50 mμ

the purple regions (see Fig. 1). It is seen that the purple (curve 2) differs from the green (curve 1) by the displacement of the maximum at 595 mμ to 555 mμ. There are also maxima at 400 mμ and, as an analysis of the curves shows, at 335 mμ and between 710 and 750 mμ. The maxima at 335 and 400 mμ were also obtained by A. Smakula[2] with artificial crystals of calcium fluoride coloured by X-rays.

As has been shown[3], the green in fluorites can be changed to grey or violet by pressure. An inverse effect has now been found in a fluorite from the Ramshaw Mine, Weardale, coloured partly green, partly lilac: careful heating turns the lilac to green, while stronger heating decolorizes the sample as usual.

In this fluorite, as in many others, and also in the Chinese one mentioned above, the green parts show stronger fluorescence under ultra-violet excitation than the violet parts. It could be proved in the case of the Chinese fluorite that this is not due to the blue light emitted (bivalent europium)[4] being more absorbed in the violet parts; on the contrary, these are more transparent to it, and they also transmit more ultra-violet light than the green parts. It seems that the green parts contain more bivalent rare earth ions than the violet ones.

At liquid-air temperature the fluorescence of the Ramshaw Mine fluorite is often blue (Eu^{++}) in the green parts and green (bivalent ytterbium) in the lilac parts; but in some samples both regions show the green fluorescence of Yb^{++}, the green parts again stronger than the lilac ones. That these samples show the Yb^{++}-fluorescence is slightly anomalous as in general it is only predominant in fluorites near acid magma[5], which is not present in the Weardale deposits. Undoubtedly, there is a variation in the relative concentration of Eu^{++} and Yb^{++} in the differently coloured regions. The thermoluminescence is also stronger in the green than in the lilac parts. These observations are in agreement with those of R. D. Allen[6], who states that green fluorites are generally more luminescent than others and relatively rich in rare earths.

In order to see if there is a connexion between colour and degree of radioactivity, Dr. Hanne Lauda, in this Institute, is testing polished slabs of green and violet striped fluorite with nuclear plates. A preliminary scanning of the plates exposed so far seems to show that there is no *strict* correlation between the colour and the very irregularly distributed radioactivity, but that in general the radioactivity is more concentrated in the darker, violet regions. What sort of colour centres are formed will depend on their stability[7], on the impurities, radioactive and inactive, and other imperfections present in the layers of growth.

I wish to thank Dr. Hanne Lauda and Mr. H. Adler for their help and the Directors of the Blanchland Fluor Mines, Ltd.—and especially Mr. E. Godfrey, mine manager—for their gift of fluorspar specimens and an interesting visit to the Ramshaw Mine, Weardale.

A more detailed report will be presented in due time to the Austrian Academy of Sciences.

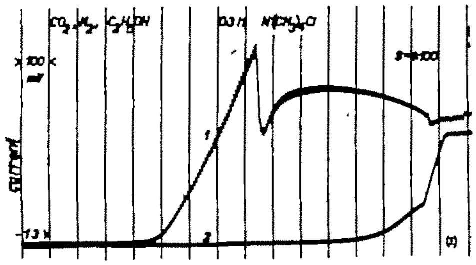
Polarographic Effect of Carbon Dioxide in Solutions of Ethyl Alcohol

A POLAROGRAPHIC depolarization effect due to carbon dioxide in aqueous solutions occurring at − 2·2 V. (from the normal calomel electrode) has been described by Van Rysselberghe[1] and v. Stackelberg[2]. This effect is, however, indistinct. When using absolute (99·8 per cent) ethyl alcohol with 0·3 *M* tetramethyl ammonium chloride in electrolysis with the dropping mercury cathode, a well-defined wave with a maximum at − 2 V. (Fig. 1) is formed on the current-voltage curve. The behaviour shows it to be due to the evolution of hydrogen from carbonic acid, the carbon dioxide molecule being regarded as not reducible. Here nitrogen containing 4 vol. per cent of carbon dioxide was bubbled through the solution for 3–4 min. at room temperature. The equilibrium concentration of carbon dioxide dissolved under its pressure in the gaseous phase is attained very quickly (in about 2 min.). The ensuing limiting current is strictly proportional to the partial pressure of carbon dioxide.

If the gas contains besides carbon dioxide also oxygen, the current-voltage curve reveals the two oxygen waves as well; however, the carbon dioxide wave is diminished as the amount of oxygen is increased. This diminution is evidently caused by hydroxyl ions, produced in the electro-reduction of oxygen, which join the acid to form the non-reducible carbonate ions, CO_3''.

The diminution of the carbon dioxide wave is to a large extent removed when hydrochloric acid is added to make the 0·3 *M* tetramethyl-ammonium chloride solution 0·015 *M* in hydrochloric acid. The hydroxyl ions formed in the reduction of atmospheric oxygen are then entirely neutralized, so that no



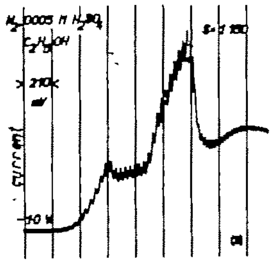


Fig. 1. (1) Current-voltage curve obtained in an atmosphere of nitrogen, the electrolyte being 0·3 *M* tetramethyl ammonium chloride in 99·8 per cent ethyl alcohol. (2) Curve after bubbling with nitrogen containing 4 vol. per cent carbon dioxide. Curves start at − 1·3 V. Abscissæ 100 mV., sensitivity 1 : 200

Fig. 2. Current-voltage curve obtained in an atmosphere of nitrogen in ethyl alcohol containing 0·3 *M* tetramethyl ammonium chloride with 0·005 *M* sulphuric acid. Abscissæ 210 mV., sensitivity 1 : 150

carbonate ions may be formed. These conditions are suitable for a continuous automatic record of carbon dioxide in gases.

The evolution of hydrogen due to hydrochloric acid yields in absolute alcohol in the absence of oxygen a wave at − 1·5 V., evidently due to the deposition of free hydrions, while the wave of carbon dioxide remains at − 2 V. Practically the same polarogram with two waves is obtained when, instead of hydrochloric acid and carbon dioxide, the ethyl alcohol contains sulphuric acid in equivalent concentration (Fig. 2). Here evidently both waves are due to the evolution of hydrogen, which is deposited in the first wave, at − 1·5 V., from free hydrions, and in the second wave, at − 2 V., from the complex HSO_4^-.

Hence it is concluded that the polarographic wave shown in the presence of carbon dioxide is also due to the evolution of hydrogen from complex particles of solvated carbon dioxide, like HCO_3^-, H_2CO_3, $C_2H_5HCO_3$.

A New Method of Separation of Organic Compounds

During attempts to purify a yellow crystalline compound obtained from acetone extract of resin, *Canarium strictum* Roxb., which could not be purified either by recrystallization with various solvents and mixtures of solvents or by chromatography over alumina and calcium sulphate, a new method of separation of organic compounds by fractional crystallization on filter paper has been developed.

Schonbein[1] and Goppelsroeder[2] were the first to utilize the separation effected by capillarity, in analytical work on organic compounds which they called "capillary analysis". After our unsuccessful attempts to purify the yellow crystalline compound mentioned above, we considered that the separation may be better effected on filter paper where capillary action would be more pronounced and fractional crystallization might occur with the added aid of capillary analysis. One would have expected that such a phenomenon would have been noticed during the early work of Schonbein and Goppelsroeder (*loc. cit.*).

To test the above view, a filter-paper strip was suspended in a 1 per cent solution of the yellow crystalline compound mentioned earlier, and exposed to the atmosphere. After half an hour, it was noticed that part of the substance had travelled up the filter paper. The resinous component remained in the pores of the filter paper and had travelled about half an inch clear of the crystalline compound. The melting point of the crystalline compound rose from 155° C. to 165° C., which on further irrigation on a fresh strip rose to 179–180° C. and remained constant. A number of experiments were conducted both with this mixture and mixtures of known compounds to evolve a general procedure for carrying out the separation. The method consists of two distinct steps.

(1) The deposition of the mixture on filter paper.

(2) Irrigating the filter paper with a pure solvent or a mixture of solvents to obtain separate zones of the components constituting the mixture.

The first step is accomplished by taking the mixture in a volatile solvent in an open dish and suspending vertically a filter paper strip (2 in. × 8 in.) (Whatman No. 3) so that its lower end dips in the solution, which is then allowed to evaporate until about 0·5 gm. of the mixture is deposited at the lower end. The dish containing the solution is now replaced by pure solvent or mixture of solvents and the system is enclosed in a bell jar, having a small opening

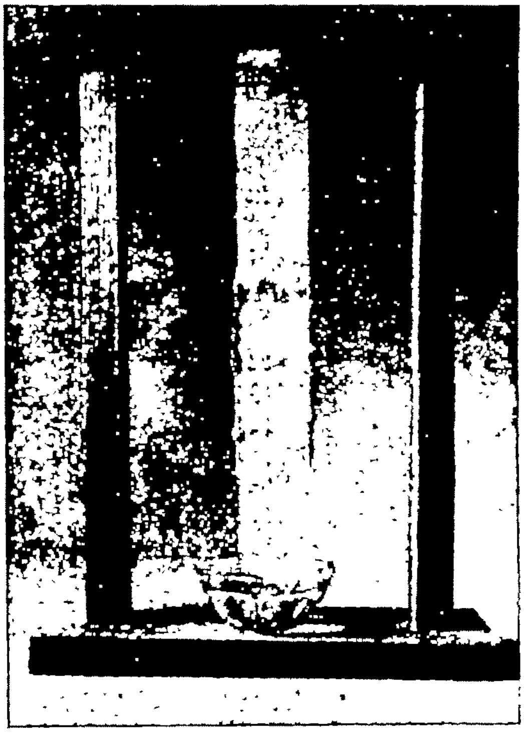

Fig. 1

at the base for steady evaporation. The rate of evaporation can be controlled by adjusting this opening. During the course of the next few hours, when no attention is necessary, part of the mixture travels farther up, forming a distinct zone (see Fig. 1). It is important that this process should be stopped at this stage, otherwise the lower zone also will rise and the separation obtained earlier is lost. The filter paper is cut in between the two zones and each run separately until pure fractions are obtained.

Using the above method, some known mixtures, (1) phenanthrene and anthracene, (2) naphthalene and bi-phenyl, (3) α-naphthol and β-naphthol, (4) hydroquinone and resorcinol, were easily separated. Hydroquinone and resorcinol, however, crystallized so well within the pores of the filter paper that one could not scrape them off without tearing the filter paper. Using wider strips, it is easy to separate larger quantities of substances in a short time.

Phenylation, Benzoyloxylation and Halogenation of Aromatic Compounds by Silver Benzoate – Halogen Complexes

Although the reaction between halogens and the silver salts of carboxylic acids constitutes a fairly well-known method for the preparation of organic halides, its mechanism is far from clear. Several types of intermediate have been isolated or postulated by different workers[1-3]. Simonini[3] obtained complexes which he formulated as $(RCO_2)_2AgX$ (where $X =$ halogen), for example, the so-called 'silver iodide dibenzoate'. Birckenbach and Meisenheimer[4] examined the decomposition of certain of these complexes in the presence of benzene, using a reaction between one equivalent of the silver salt and two equivalents of iodine. The formation of iodobenzene and the phenyl ester of the acid was reported. From a reaction between silver *p*-chlorobenzoate and iodine in boiling chlorobenzene, *p*-chlorophenyl *p*-chlorobenzoate was isolated. In this latter case, it is not clear from the experimental evidence whether the ester resulted from a reaction with the solvent, or whether both its *p*-chlorophenyl groups originated in the silver salt. It is known that esters, RCO_2R, can result from analogous reactions between silver salts, RCO_2Ag, and iodine[5]. A preliminary investigation of this subject has exposed several interesting new features, which are now briefly described.

Silver benzoate has been suspended in a number of aromatic compounds and treated with one equivalent of bromine or iodine at 20°. The resulting insoluble complex has been caused to decompose by heating at 80° (Br) or 130° (I). Silver iodide dibenzoate decomposes in chlorobenzene at 130° with the evolution of carbon dioxide and the formation of a mixture of isomeric chlorodiphenyls (22 per cent), chlorophenyl benzoates (5 per cent) and benzoic acid (35 per cent); the iodine appears almost quantitatively as silver iodide. Reduction of the chlorodiphenyls with Raney nickel gave diphenyl, and bromination gave a little 4-bromo-4′-chlorodiphenyl, melting point and mixed melting point 154–155·5°. The relative proportions of phenylation and benzoyloxylation in this experiment are similar to those which are found in the decomposition of benzoyl peroxide in aromatic solvents[6], and suggest a common basic mechanism, namely, the formation and subsequent decarboxylation of free benzoyloxyl radicals, $C_6H_5CO_2\cdot$.

In contrast, the decomposition of silver bromide dibenzoate in chlorobenzene leads to benzoyloxylation only, and not to any appreciable degree of phenylation. Of the mixture of chlorophenyl benzoates which was obtained (23 per cent), 30 per cent of the *para* isomer was readily isolated by crystallization: the true proportion was certainly higher than this. Only 70 per cent of the bromine appears as silver bromide. In nitrobenzene, silver bromide dibenzoate decomposes to give a mixture of nitrodiphenyls and *m*-nitrophenyl benzoate in approximately equal proportions. Little, if any, of the *para* ester is produced, for a blank experiment showed that the working-up process would tend to concentrate this isomer. The orientation in these benzoyloxylation experiments is regarded as a significant indication of their electrophilic character and of the intermediacy of benzoyloxyl cations—a hitherto unknown species. Unfortunately, the orientation in the homolytic benzoyloxylation of benzene derivatives is not yet known, and direct comparison with the present results is not possible. In homolytic phenylation and hydroxylation, *meta* positions are known to be relatively unreactive, and the effect of substituents in the aromatic ring is small. A homolytic mechanism for benzoyloxylation by silver bromide dibenzoate is therefore regarded as improbable. It may be noted in passing that this reaction represents a method for the direct oxidation of the aromatic nucleus.

Another type of reaction is illustrated by the decomposition of silver bromide dibenzoate (prepared in *n*-heptane) in anisole. This gives *p*-bromoanisole as the principal high-boiling product; but slight benzoyloxylation of the anisole also occurs. Silver iodide dibenzoate and silver iodide diacetate oxidize *iso*propylbenzene to acetophenone at 100°; the yields are low.

It is already clear that a common mechanism cannot be advanced for all reactions which involve halogens and the silver salts of carboxylic acids; but it is felt that detailed considerations should await the results of further experiments. An account of these will be given elsewhere in due course.

I would like to acknowledge the interest shown in this work by Prof. D. H. Hey and Dr. G. H. Williams. The work is being carried out during the tenure of an I.C.I. Research Fellowship at the University of London.

Thermal Anomaly in the Elastic Constants of Chromium

SEVERAL investigators[1,2] have shown that at a temperature near 37° C. anomalies exist in some of the physical properties of pure chromium. In an earlier communication[3], we reported measurements which had been made here of the variation with temperature of the Young's modulus and modulus of rigidity of an electroformed tube of chromium which had been annealed for fifteen hours at 544° C., showing that a sharp minimum occurred near 37° C. in the velocity of propagation of longitudinal waves, corresponding to a fall in elastic modulus of about 2 per cent when measured on the fundamental vibration, but only to about 1 per cent when measured on the 8th harmonic. The modulus of rigidity–temperature curve showed only a small stationary region of modulus over a range of about 6° C. above the temperature of minimum longitudinal modulus, similar results being obtained on all measured harmonics.

We have now made considerable progress in investigating the transition in Young's modulus with temperature in various types of chromium, and can correct our former interpretation of the apparent frequency dependence of the anomaly, which is now seen to be due to invariance of the modulus of rigidity through the transition temperature and the consequent change in Poisson's ratio of the material.

In a paper by Fine, Greiner and Ellis[1] the authors suggest that the anomaly in Young's modulus may be related to the anomaly which has been observed in the volume expansivity of the material[1,2]. This anomaly occurs at a temperature which decreases with compressive stress, and so we may expect that the application of such a stress will cause the material to change towards the high-temperature modification, thereby producing an anomalous bulk strain in addition to the normal elastic strains. This extra strain will add to the elastic strain along the stress axis, but will tend to neutralize the strains normal to this axis, so that Young's modulus and Poisson's ratio will be simultaneously reduced. The reduction in Poisson's ratio will also reduce the dispersion which occurs on longitudinal waves[4-6], since it implies a reduction in the lateral component of vibration, and the difference between the velocities measured at low and high frequencies will therefore decrease as the temperature of the anomaly is approached. This means that the velocity as measured on higher harmonics will increase relative to that measured on the fundamental frequency, thus reducing the anomalous change in velocity on the higher harmonics. It should be added that direct evidence for the reduction in Poisson's ratio has been obtained from static extensometer measurements of lateral strain under a uniaxial stress, and it has been found that in certain impure samples of chromium the value of Poisson's ratio may actually become negative.

We have studied the effect of impurities on the transition, including iron, silicon, nickel and copper, and have shown that in general the transition will occur at a lower temperature in an impure material than in a pure sample. So far no impurity has been found which raises the transition temperature. The reduction in transition temperature and the magnitude of the change in modulus vary greatly with the type of impurity, and in the case of iron it has been found that the reduction in temperature is roughly proportional to the amount of impurity present. In other cases there is also a large increase in the extent of the change in modulus, which may sometimes be as much as 1·5 : 1. These large anomalies have been observed mainly in specimens containing silicon.

It is intended to publish a full account of this work when completed. In conclusion, I should like to acknowledge several helpful discussions with Dr. E. A. Calnan, and the large part played by Mr. J. H. Rendall, of the Metallurgy Division of the Laboratory, and Dr. A. H. Sully, of the Fulmer Research Institute, in the work of preparing specialized specimens.

The work described above has been carried out as part of the research programme of the National Physical Laboratory, and this communication is published by permission of the director of the Laboratory.

The Lambda Wave as a Normal Physiological Phenomenon in the Human Electroencephalogram

SEVERAL recent communications[1,2] have described a hitherto unobserved phenomenon in the human electroencephalogram. This consists of random monophasic waves ('lambda waves'), appearing when the eyes are open, in the occipital or parietal regions. The phenomenon is believed to be rare, and a relationship to pathological conditions such as epilepsy or organic disease of the brain has been suggested. We have, however, recently obtained evidence suggesting that it is probably a normal physiological phenomenon which may be frequently unobserved owing to its very low voltage, its masking by background activity or both.

In the course of an investigation of the electroencephalogram changes produced by pre-frontal leucotomy, waves were observed after the operation which were identical with those described by Evans, in form and distribution, but considerably greater in amplitude (Fig. 1). A re-examination of the series of records obtained in each case revealed, however, that in two-thirds of the patients the phenomenon was already present, though at lower amplitude in the barbiturate record before operation. Moreover, in a small proportion of patients it was seen in the electroencephalogram recorded in the waking state before and after leucotomy.

In the group of psychiatric patients investigated there was little reason for anticipating any abnormality either in the barbiturate record or in the ordinary electroencephalogram. It seemed worth while, therefore, to look into the possibility that the occipital lambda wave might be a physiological phenomenon present at a low though variable amplitude in the normal subject, and rendered more prominent by barbiturate anaesthesia and, for a period, by pre-frontal leucotomy. This unmasking of an activity absent from the electroencephalogram in

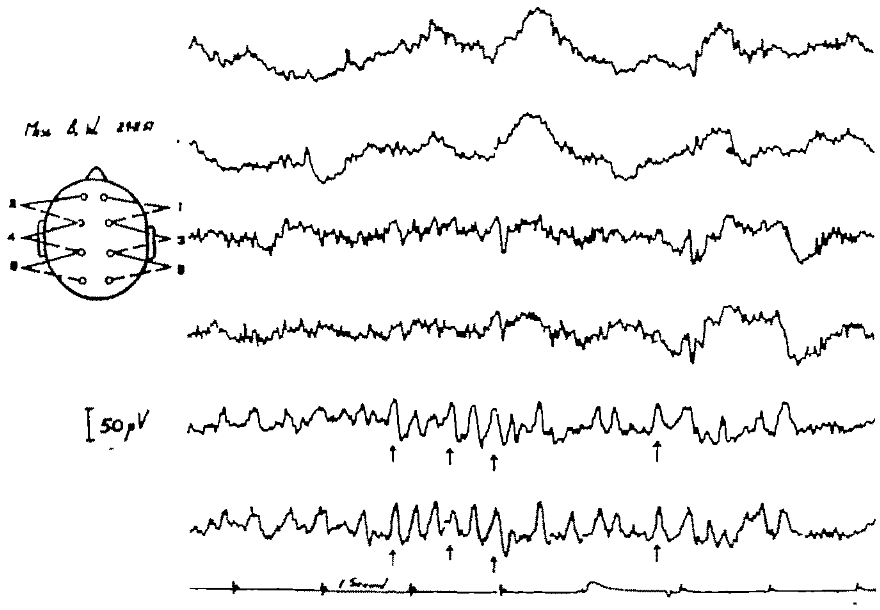

Fig. 1. Electroencephalogram under barbiturate anaesthesia showing prominent lambda waves in the occipital areas (marked with arrows in places) in a patient eight days after prefrontal leucotomy

the waking state, or its enhancement when present during consciousness at low voltage, is a well-known effect of barbiturate anaesthesia on some other phenomena in the electroencephalogram[3,4].

Electroencephalograms of thirty-seven normal adult subjects whose ages ranged from sixteen to fifty-six have been studied. Special attention was paid to the effects of long periods of maintaining the eyes open, of stimulation with a flickering light, visual scanning of plain, patterned and printed cards, and of attention and mental effort. Lambda waves were found in the waking state in twenty-seven of the thirty-seven subjects. In the majority of these the phenomenon was present in poorly sustained form at very low amplitude and was distinguished with difficulty from background activity. But opening the eyes following 20–30 sec. of stimulation with a flickering light at about twenty flashes per second evoked the phenomenon for 4–6 sec. in a more clearly defined form and at higher voltage in most subjects. Six of the subjects, two of them with, and four without, the lambda waves in the waking state, have been examined under light barbiturate anaesthesia (0·25 gm. sodium thiopentone). Lambda waves were demonstrated in the barbiturate record of all six subjects. In the two subjects whose ordinary records had shown lambda waves, the latter were greatly increased in amplitude in the barbiturate-record, though identical in form with those observed in the waking state.

The findings suggest that the lambda waves are a physiological phenomenon in the human electroencephalogram which, however, can be elicited in many cases only with the use of special methods of examination. Confirmation for this view has been obtained by a recent observation of lambda waves during ordinary sleep in one normal subject and five psychiatric patients. That the waves we have observed in the barbiturate record are homologous with those described by Evans is suggested by (*a*) their similarity in form; (*b*) their random arrhythmic character; (*c*) the fact that when the phenomenon is located in the parietal, occipital or parieto-occipital regions in the waking state, their distribution is nearly always identical in the barbiturate record (Fig. 2).

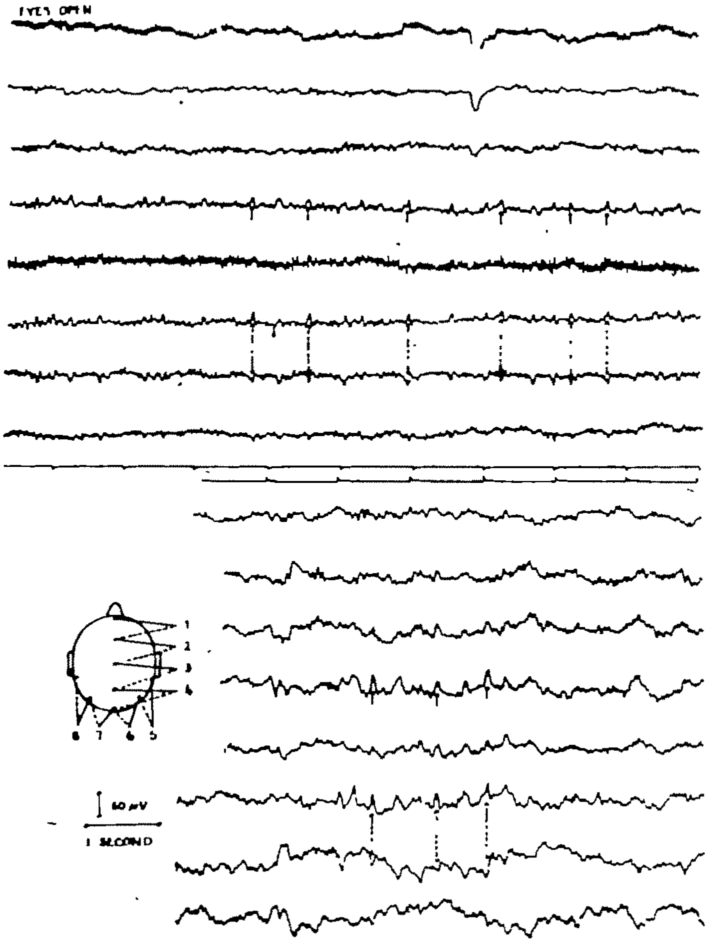

Fig. 2. Records taken during consciousness (above) and under light barbiturate anaesthesia (below) showing occipital sharp waves of similar distribution and a phase-reversal between leads 6 and 7 in each case

The phenomenon is suppressed when the room is darkened or the patient asked to focus on a near object or to gaze at a plain white surface. But looking at a patterned or printed card did not consistently evoke or enhance the phenomenon as in Evans's experiments. When the patient was asked to scan a patterned or printed card as in reading, the phenomenon was almost invariably evoked or augmented; but it was reduced on scanning a sheet of white paper. The same result was obtained with either eye covered. The results would appear at first sight to confirm Evans's view that the waves are provoked by abrupt changes in the afferent impulses that occur as the focus of macular vision moves over areas of varying brightness. But the relationship with macular stimulation, if any, does not appear to be a specific one even during consciousness. Thus we have repeatedly observed the appearance of the phenomenon following cessation of the mental effort involved in solving a problem. The presence of lambda waves at enhanced amplitude during barbiturate anaesthesia is also evidence against any specific association with visual perception or hallucination[3] or mental activity. However, these problems, as also the apparent change in the prominence of lambda waves after pre-frontal leucotomy, are matters for further investigation.

Effect of Melanophore Hormone on Regeneration of Visual Purple in Solution

JORES[1] considered that melanophore hormone might have a role in night vision, first because nocturnal animals have more melanophore hormone in their hypophysis than diurnal ones; secondly, because the amount of the hormone increases on dark-adaptation; and thirdly because, apart from the hypophysis, the hormone is concentrated only in the eye and thalamus. He presumed that the function of the hormone was to act as a catalyst for the regeneration of visual purple.

By injecting a highly purified fraction of melanophore hormone subcutaneously, I have shown[2] that this hormone not only shortens the time of dark adaptation but also considerably increases the sensitivity in man. Furthermore, the melanophore hormone was found[3] to have an augmentative effect on the regeneration of visual purple *in situ*, using Japanese toads (*Bufo vulgaris formosus*) into the lymph heart of which the hormone was injected.

Although melanophore hormone accelerates the *in vivo* regeneration of visual purple, we do not know whether this is due to direct participation in the regenerative process or indirectly by influencing some retinal condition (for example, blood circulation) favourable to regeneration. Some experiments have accordingly been carried out to ascertain how the hormone would act on visual purple itself. At least five frogs (*Rana nigromaculata*) were decapitated after two hours of dark-adaptation and the eyes enucleated and dissected equatorially under a dim red light in a dark room. The visual purple was extracted with 2–3 ml. of sodium-cholate solution. The extract was divided into three equal portions. To two of these portions was added a certain volume of distilled water, while to the third was added a similar volume of melanophore hormone (extracted from the hypophyses of male and female frogs and containing about 50 I.U. per ml.). Each portion of the visual purple solution was then neutralized with 0·1–0·2 ml. of 0·1 *M* phosphate buffer. All three solutions were then exposed to 1,500 lux for 10 sec., which reduced the visual purple content to about 75 per cent of that initially present.

Immediately after bleaching, the portion containing melanophore hormone and one of the control portions were incubated in the dark, the other control portion being used for a determination of visual purple content. After incubation for about two hours the amounts of visual purple in the other portions were determined. The amounts of visual purple present were obtained by measuring the change in density occurring on exposure to light. The density measurements were made near the absorption maximum using a filtered light of dominant wave-length 517 mμ (bandpass width, more than 20 per cent transmitted; 460–588 mμ)[4]. The results obtained are shown in the table.

Exp. No.	Vol. of melanophore hormone added to visual purple solution	Visual purple bleached	Visual purple regenerated			
			Control		Proof	
			Opt. density	Per cent	Opt. density	Per cent
5	0·2–0·65 ml.	0·052	0	0	0·003	5·8

* Negative values indicate degeneration.
† In these experiments the visual purple was extracted from the outer segments of the rods by Kimura's method (ref. 4).

It is clear from the table that whereas in the controls the amount of visual purple is either only slightly increased, or it may even be degenerated during the incubation period, some regeneration always occurs in those solutions containing melanophore hormone and always to a greater extent than in the controls. This indicates that melanophore hormone has an effect on the regenerative process. The very large amount of regeneration observed in experiment No. 10 suggests that there may exist some factor which co-operates with melanophore hormone very effectively. A study of the effect of various factors on the potency of melanophore hormone is now in progress.

Effect of Rauwolscine on the Action of Adrenaline on Blood Pressure

RAUWOLSCINE ($C_{21}H_{26}O_3N_2$), the active principle of *Rauwolfia canescens*, has been isolated by Chatterjee, and its chemical nature has been studied[1,2]. The pharmacology of this alkaloid has recently been investigated by Mukherjee and Sen[3,4]. This compound has been found to be hypotensive. I have observed that the intravenous injection of 1 mgm. per kgm. of body weight of rauwolscine completely annuls the action of adrenaline on blood pressure in cats when injected intravenously in 1 c.c. doses of 1 : 100,000, 1 : 50,000, 1 : 20,000 and 1 : 10,000 strengths of adrenaline. This antagonistic action of rauwolscine to adrenaline has also been studied on amphibian and mammalian isolated heart muscles by perfusion technique. The normal amphibian and mammalian hearts are always stopped when perfused with 1 c.c. of 1 : 1,000 of adrenaline (P.D.). These hearts cannot be revived. 1 c.c. of 1 : 20,000 dilution of rauwolscine can, however, check this toxic action of adrenaline on the heart. Rauwolscine cannot counteract the glycogenolytic action of adrenaline. The mechanism of action of rauwolscine against adrenaline is now being investigated in detail.

I am indebted to Prof. A. Chatterjee, professor of chemistry, Lady Brabourne College, for kindly supplying the rauwolscine for this experiment.

A New Type of Autonomic Blocking Agent

THE useful autonomic ganglionic blocking agent hexamethonium, and some of its closely related derivatives, possess quaternary ammonium nitrogen atoms. The activity of the compounds of this type has commonly been associated with the quaternary ammonium salt structure. Certain side-effects of drugs of this type may also be attributed to their quaternary salt nature. In exploring a series of compounds related to *W.R.L.* No. 51–143, 1-methyl-3-(δ-dimethylaminobutyl)piperidine dihydrochloride, it was discovered that powerful ganglionic blocking activity is also possessed by tertiary amines. The importance of this discovery lies in the facts that not only are these tertiary amines at least as potent and much less toxic than hexamethonium derivatives, but also, lacking the quaternary salt groups of the latter compounds, they should be free of many of the aforementioned side-effects.

On intravenous injection in anæsthetized cats and dogs, *W.R.L.* No. 51–143 blocks the autonomic ganglia and causes falls in blood pressure comparable to those obtained with hexamethonium chloride. Injected epinephrine is not blocked. On oral administration, equimolar doses of *W.R.L.* No. 51–143 last longer than hexamethonium in lowering the blood pressure.

Other tertiary amines and quaternary ammonium salts of the same series are also being investigated. Detailed pharmacological and chemical reports on this group of substances will be made elsewhere.

Extensive work is in progress to exploit these findings by the examination of numerous other related series of compounds of quite varied structures.

Urinary Excretion of Acid and Neutral Deoxyribonuclease by Rats under Normal and Post-Irradiation Conditions

INTEREST in devising methods of studying tissue breakdown after irradiation has led us to investigate the deoxyribonucleases in body fluids on the premise that these enzymes are liberated only by damaged or destroyed cells. We have reported previously on the increased urinary excretion of the neutral deoxyribonuclease by rats exposed to lethal doses of X-rays[1]. The purpose of the present communication is to describe a similar but more prompt increase in the urinary excretion of an acid deoxyribonuclease (*p*H optimum 5·6) by irradiated rats. This is the enzyme which has been studied recently *in extenso* by Allfrey and Mirsky[2]. It has been found in many tissues, especially those capable of active proliferation. The urinary acid deoxyribonuclease is partially inhibited by magnesium ion and citrate (0·1 *M*); its activity is not affected by antimony sulphate, sodium arsenate and extract of the pigeon crop gland, all of which inhibit the neutral deoxyribonuclease[3,4].

In our experiments, twelve-hour samples of urine were collected from the experimental rats before and after total-body exposure to 700 roentgens of 250-kV. X-rays[1]. The urine was diluted with an equal volume of a 1 : 100 (v/v) aqueous solution of the chelating agent, versene, in order to remove magnesium ions. One ml. of the diluted urine was buffered with 1·5 ml. of a 0·2 *M* acetate buffer (*p*H 5·6), and the solution was incubated with 0·5 ml. of a highly polymerized solution of sodium deoxyribonucleate prepared according to the method of Kay and Dounce[5]. The enzymatic reaction was stopped after three hours of incubation at 37° C. by addition of 0·8 ml. of 3·6 *M* trichloracetic acid, and the deoxypentose phosphorus was determined in the supernatant fluid of the centrifuged solution. The following data demonstrate the marked increase in the deoxyribonuclease activity after irradiation of 10 rats:

DEOXYRIBONUCLEASE ACTIVITY

	Range	Average
Before irradiation (12 hr., 1 day pre-exposure)	3·50– 7·03	4·92
After irradiation (6–18 hr. post-exposure)	15·96–33·96	23·20

The deoxyribonuclease activity is calculated for the twelve-hour collection period and is expressed as acid-soluble deoxypentose-phosphorus released per hour of incubation at 37° C.

Our results leave no doubt that there are two deoxyribonucleases in rat urine, and that the activities of both enzymes increase after total-body exposure of the animals to X-rays. These findings strongly suggest that the increased activity, particularly of the acid enzyme, is related to the destruction of radiosensitive cells.

This work will be published elsewhere in greater detail.

A Disturbance of Tryptophan Metabolism in Congenital Hypoplastic Anæmia

The clinical entity originally designated as congenital hypoplastic anæmia[1] and more recently termed erythrogenesis imperfecta[2] is a rare type of anæmia characterized by an erythroid hypoplasia of the bone marrow, by normocytic and normochromic circulating red cells, and by the lack of response to any of the known erythropoietic agents. In the course of some metabolic studies conducted on one such patient whose anæmia was diagnosed shortly after birth and who had been studied for four years by one of the authors (G. M.), a strongly bluish-fluorescent substance was noted in the urine. (This patient has been studied through the kindness of Dr. C. P. Katsampes.) This fluorescent material was identified as anthranilic acid by chromatographic methods[3], isolation from the patient's urine, and by spectroscopic techniques. The R_F of this fluorescent material was 0·90 in butanol : acetic acid : water, 1 : 1 : 5, in agreement with the R_F of a known sample of anthranilic acid. The melting point of the material isolated (144–146°) and the absorption spectrum are identical with comparable data reported in the literature for anthranilic acid.

Oral administration of 1·6 gm. of L-tryptophan led to increased urinary excretion of anthranilic acid as well as to the excretion of other intermediary metabolites of tryptophan.

On the basis of the available knowledge concerning tryptophan metabolism it was reasoned that anthranilic acid was most likely to accumulate in excessive amounts under conditions of riboflavin deficiency. This point of view has recently been confirmed by the work of Charconnet-Harding *et al.*[4] and Mason[5]. In order to test the validity of this postulate, the patient in question was treated with massive doses of riboflavin per os (200 mgm. per day for 17 days and then 100 mgm. per day for 13 days). Although no change in the hæmatological status was observed even after one month under this therapeutic regimen, there appeared to be a decrease in the amount of anthranilic acid excreted.

Specimens from eight additional cases have been made available to us and in all instances anthranilic acid could be found in the urine. (Specimens of urine from cases studied elsewhere were furnished through the kindness of Drs. I. A. B. Cathie, L. K. Diamond, E. Freshman and C. H. Smith.) In one case (specimen and information on the case furnished by Dr. L. K. Diamond) experiencing hæmatological improvement nine weeks after splenectomy, anthranilic acid was still detectable in the urine. Urinary specimens collected at random on the pædiatric ward revealed no case in which anthranilic acid was detectable in the urine.

The findings reported here are suggestive of an inborn error in tryptophan metabolism. The relationship of this metabolic disturbance to the co-existing anæmia has, as yet, not been elucidated. Studies aimed at exploring this point are now in progress. The genetic disturbance, if such exists, may be pleiotropic in nature. None of the members of the immediate family of the patient studied was found to excrete the metabolite in question. Details of this work will be published elsewhere.

This paper is based in part on work performed under contract with the U.S. Atomic Energy Commission at the University of Rochester Atomic Energy Project, Rochester, New York.

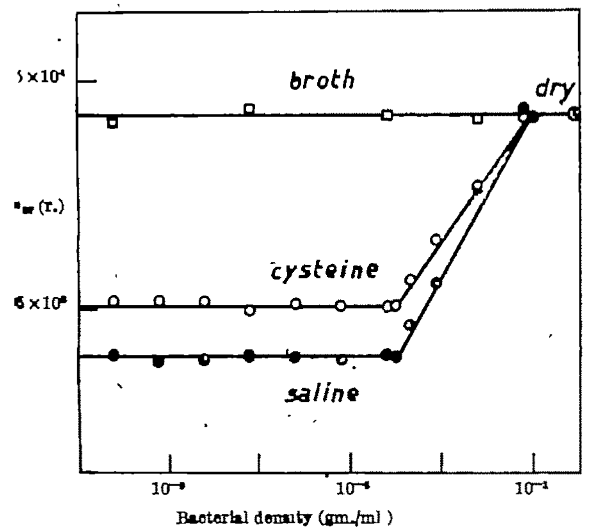
Quantitative Aspects of the Indirect Action of X-Radiation at Various Concentrations on *E. coli*

The lethal effects of irradiations with X-rays on *E. coli* have been studied. Our observations were made on bacteria dried, or suspended either in 2 per cent broth or saline solution, at bacterial densities of 10^{-1} to 10^{-10} gm./ml. Some experiments were also made by adding 10^{-3} *M* cysteine to the solutions. An X-ray tube was used operating at 110 kV., and 4 m.amp., at a dose-rate of 36 r./min., without any additional filter.

The overall configuration of the curves paralleled that observed by other authors on tobacco mosaic virus[1], rabbit papilloma virus[2] and *S*-13 *coli* phage[3]. Our results can be partly explained on the basis of widely accepted theories. On the dry bacteria and strongly concentrated suspensions, the effect is only direct; as the concentration is diminished (in the absence of broth), both direct and indirect effects occur. If the suspending medium contains cysteine, the indirect action is reduced; it disappears if the medium contains broth.

There is no clear explanation of the observation that the dose giving 36·8 per cent survival (D_{37}) is independent of the bacterial concentration, at extremely diluted cell suspensions. The hypothesis (Lea[4], p. 317), that the 'death' of a bacterium is due to a direct effect only, cannot be accepted under the conditions of our experiments. The marked difference between the D_{37} for irradiated dry bacteria and for those in water, as well as the chemical protection, necessarily require an explanation of the absence of



variability of the D_{37} for diluted suspensions within the limits of the indirect effect, taking into account the constant probability of a direct action. Therefore the 'dilution effect' during irradiation of bacteria at lower cell concentrations ceases to be a suitable criterion for distinguishing one mechanism from the other.

In other experiments that will be published *in extenso* elsewhere, it was observed that the effects of a constant amount of hydrogen peroxide (tested for concentrations of 10^{-3} to 10^{-6} *M*) against bacterial density (from 10^{-8} to 10^{-1} gm./ml.) are not the same quantitatively as the effects of a constant dose of radiation. In the light of these results, we do not think that a biological activity (such as the *E. coli* catalase activity) can partly neutralize the chemical effects of radiations in such a way as to justify the quantitative characteristics observed. Moreover, the observed behaviour of the D_{37} cannot be explained on the basis of the kinetics of radical recombination[4,5].

If we consider each element separately and its relationship with the free active radicals, it is possible to offer an interpretation. Taking into account the indirect effect only, we observe that the absolute weight of bacteria reacting with a given dose diminishes from 10^{-1} to 10^{-4} gm./ml. of bacterial density, owing to the recombination of free radicals. Radical combination increases progressively, but in a lesser degree than the diminution of the bacterial density; consequently, the relative effectiveness of radiation is enhanced. This appears to be due to the fact that, by decreasing the bacterial density, each individual cell is subjected to the action of an increasing number of active radicals. But this effectiveness does not increase indefinitely. At a given cell concentration a limit would be reached, which represents the maximum indirect action for a given number of active radicals. It can be assumed that the lower inflexion of the D_{37} line (corresponding to 10^{-4} gm./ml. for the *E. coli*) is related to the distance between the separate entities. According to this interpretation, the point of inflexion is to be expected at a higher concentration when the irradiated object is larger. In the light of the above results and of the experimental results[1-3], there would appear to be a relationship between the critical concentration and the size of the cell. If this quantitative relationship is independent of the nature of the irradiated object as well as of the characteristics of the chemical changes which cause the observed effect, analogous behaviour is to be expected by irradiating chemical substances of various molecular weights.

Further studies on the behaviour of micro-organisms in comparison with chemicals of different molecular weight are being undertaken to substantiate the hypothesis.

Fuller details of this work will be published elsewhere.

Morphogenetic Interaction between Embryonic Mouse Tissues separated by a Membrane Filter

IN analysing inductive interaction between parts of developing systems several investigators[1] have interposed barriers of various sorts to distinguish between effects due to direct cellular contact and those due to diffusion. No morphogenetic effect has been demonstrable in particular cases through 'Cellophane', vitelline membrane or cigarette paper. In studies of epithelio-mesenchymal interaction in cultured mouse embryo rudiments we have recently employed so-called membrane or molecular filters[2] for similar purposes and have noted two morphogenetic effects across them. The present brief report is to record these results as a suggestion of possible broader usefulness of filters of this type in problems of embryonic induction.

Thirteen-day-embryo submandibular and eleven-day-embryo metanephric rudiments of the mouse can be separated into epithelial and mesenchymal components following 5–10 min. exposure to 3 per cent trypsin (desiccated powder, 1 : 300, in calcium–magnesium-free Tyrode's solution)[3]. An epithelial component explanted in a cluster with mesenchyme fragments from its own rudiment type (autogenous) undergoes morphogenesis in characteristic fashion; a similar component explanted with generalized mesenchyme or mesenchyme from other rudiments (heterogeneous) forms only a spheroidal mass or simple cyst. On the other hand, eleven-day-embryo metanephric mesenchyme (nephrogenic cord), which forms tubules during normal development under the influence of the metanephric epithelium (ureteric bud), produces coiled tubules when combined in culture with its own epithelium, submandibular epithelium or embryonic spinal cord, but fails to do so when cultured in isolation.

To test for possible diffusible effects in these interactions, appropriate tissues have been cultured on either side of 4-mm. square molecular filter sheets (Millipore, *HA*, 20 µ thickness, Lovell Chemical Co., Watertown, Mass.). (I am grateful to Drs. Glenn Algire and Richmond Prehn, of this Institute, for bringing the filters to my attention, and to W. B. Krabek, of the Lovell Chemical Co., for supplying test material.) Fragments of one tissue were placed on the surface of a chicken plasma clot, covered with the filter, and fragments of the second tissue superimposed over the first in a second clot on top of the filter. The 20-μ filter is sufficiently translucent to allow accurate superimposition of the two tissues.

The culture vessels were small, flat, loosely covered glass dishes with a central well in which the clot (rooster plasma and nutrient fluid. 1 : 1) was made. Over the clot was layered supernatant nutrient fluid containing horse serum, Tyrode's solution and chick embryo juice (2 : 2 : 1). The supernatant fluid, which included 5 mgm. per cent each of penicillin and streptomycin, was replaced every second day. The covered dishes were incubated at 37·5° C. in containers filled with 5 per cent carbon dioxide in air. The procedure, which gave good morphogenesis of early intact rudiments, appears to combine certain of the advantages of the watch-glass and Carrel flask techniques.

The behaviour of submandibular epithelium directly recombined with its own mesenchyme, or separated by a filter from its own or heterogeneous mesenchyme, is shown in Fig. 1. When isolated from mesenchyme the epithelium spreads as a thin sheet or, at most, forms abortive processes; with heterogeneous mesenchyme on the opposite side of the filter it rounds into a cyst; with autogenous mesenchyme on the opposite side of the filter (Fig. 1 *C*) it undergoes process formation of variable morphology, reminiscent of, but clearly differing in detail from, the characteristic *in vitro* behaviour (Fig. 1 *A*). It thus appears that, without direct cellular contact (Fig. 2), mesenchyme can prevent spreading and disorganization of the epithelial rudiment and, depending on the specific character of the mesenchyme, alter the epithelial morphogenetic behaviour. It is of interest, however, that autogenous mesenchyme separated from epithelium by a filter does not, on the basis of present results, produce reactions equal to those produced by directly associated autogenous mesenchyme.

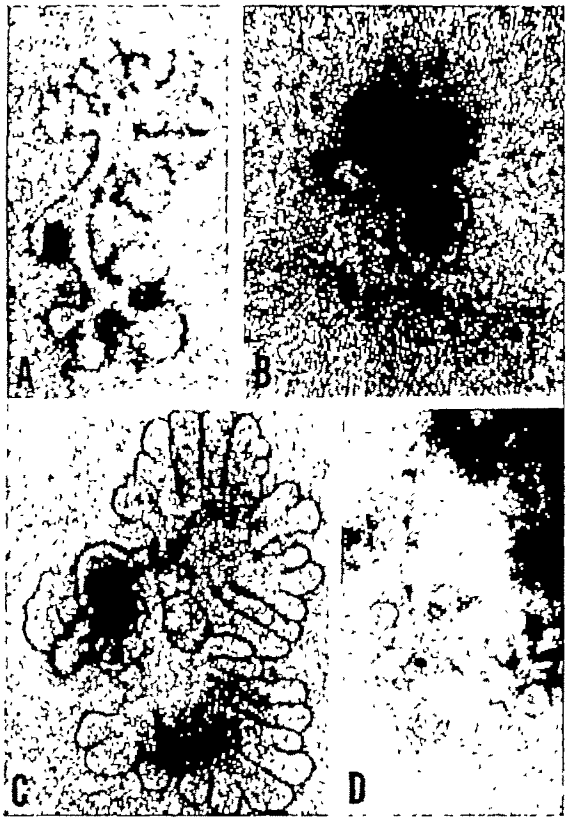

Fig. 1. *A*, Submandibular epithelium undergoing morphogenesis in culture after isolation and recombination with autogenous mesenchyme. Third day of culture (× 32)
B, Submandibular epithelial rudiment on top of filter, heterogeneous (from maxillary region of 13-day embryo) mesenchyme below. Third day in culture. No morphogenesis, final product an inflated cyst (× c. 27)
C, Submandibular epithelial rudiment on top of filter, autogenous mesenchyme below. Definite but atypical morphogenesis. Fourth day in culture (× c. 27)
D, 13-day-embryo spinal cord fragment (out of focus) on top of filter, coiled tubule rudiments forming below in metanephric mesenchyme. Fourth day in culture. (× 32)

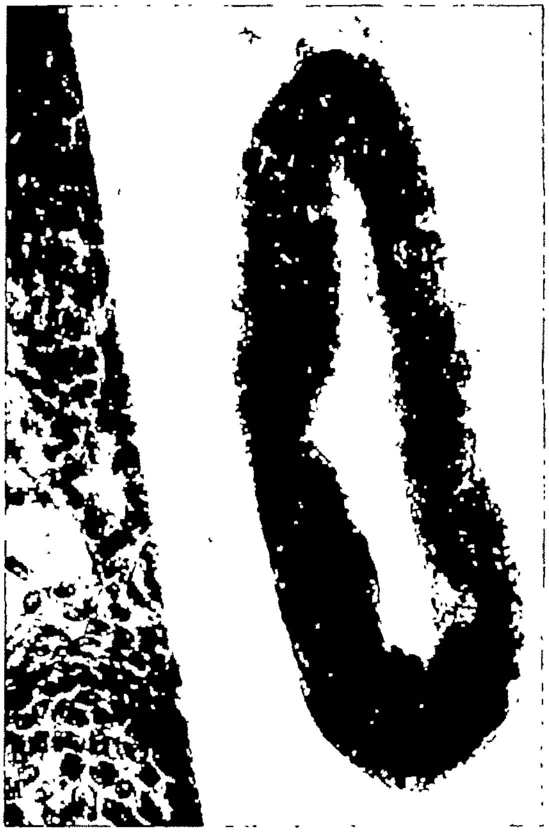

Fig. 2. Fixed and stained cross-section through heterogeneous mesenchyme (left), filter (centre) and epithelial rudiment (right). This is the same culture as in 1,*B*, fixed on sixth day. (× 340)

While it is clear that heterogeneous mesenchyme exerts a filter-passing inhibitory influence on submandibular morphogenesis, it is not yet clear whether autogenous mesenchyme exerts filter-passing positive morphogenetic effect. Such an effect is noted, however, when thirteen-day embryo spinal cord fragments are placed on one side of the filter with metanephric mesenchyme fragments on the other. In a significant number of cases coiled tubules, similar to those forming in the mesenchyme of intact cultured metanephric rudiments and in metanephric mesenchyme directly combined with embryonic spinal cord, appear in the mesenchyme above the filter (Fig. 1 *D*).

It thus appears that membrane filters, now becoming available in various thicknesses and porosities, may prove a useful tool for disentangling and characterizing the diffusible and non-diffusible components of inductive processes.

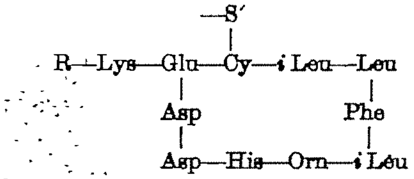
Structure of Bacitracin *A*

A BACITRACIN polypeptide purified by charcoal chromatography was shown by ultracentrifugation to have a molecular weight of 1,400–1,500 [1]. Recently, by a modified procedure using milder conditions, a peptide of higher antibiotic potency (about 60 units/mgm.) was isolated from a cruder starting material than was previously used. Except for higher activity, this peptide has essentially the same properties as that previously studied. This preparation was compared with a specimen of bacitracin *A*[2] kindly supplied by Dr. L. C. Craig, and appears to be identical with it. Ultracentrifugation of bacitracin *A* indicated a somewhat lower molecular weight (1,390), but the difference is probably not significant. The most potent fraction obtained from charcoal will therefore be referred to as bacitracin *A*.

Independently of Newton and Abraham[3] and Craig *et al.*[4], I found that the sulphur atom is probably involved in a labile heterocyclic structure, possibly a thiazoline or thiazolidine ring. In any event, no —S—S— bridges were found by polarography and no indication of dimerization was detected by ultracentrifugation during conditions where this was expected to occur. With the exception of ornithine and histidine, all the amino-acids present in bacitracin *A* were found in hydrolysate from the fully substituted DNP derivative. Lysine was found to be unaffected by Sanger's reagent[5]. No DNP-leucine or DNP-*iso*leucine was found (contrary to the findings of Newton and Abraham), and the method of Edman[6] did not reveal any N-terminal amino-acid. These facts indicate the cyclic nature of bacitracin and the presence of heterocyclic rings.

In order to obtain further information about the structure, bacitracin *A* was partially hydrolysed by 1*N* hydrochloric acid for 72 hr. at 37° C. The resulting peptide mixture was fractionated by successive application of zone electrophoresis and charcoal and paper chromatography. The details of the methods will be published elsewhere. Many of the peptides yielding glutamic and aspartic acids and cystine on hydrolysis were difficult to isolate. After evaporation of the solvent, these peptides often are converted to insoluble products. Complete hydrolysis of a ninhydrin-positive substance (obtained by partial hydrolysis) gave only lysine and an unknown compound which is ninhydrin-negative (but gives a yellow spot on paper chromatograms after heating). The ε-amino group of lysine must therefore be linked to this, as yet, unidentified compound. The observations indicate that the amino-acids of bacitracin are interconnected in the following order:



$$\begin{array}{cccccccccccc} & & & & & & \text{—S}' & & & & & \\ & & & & & & | & & & & & \\ \text{R} & \text{—} & \text{Lys} & \text{—} & \text{Glu} & \text{—} & \text{Cy} & \text{—} & i\,\text{Leu} & \text{—} & \text{Leu} & \\ & & & & | & & & & & & | & \\ & & & & \text{Asp} & & & & & & \text{Phe} & \\ & & & & | & & & & & & | & \\ & & & & \text{Asp} & \text{—} & \text{His} & \text{—} & \text{Orn} & \text{—} & i\,\text{Leu} & \end{array}$$

The lysine, glutamic acid and cysteine residues are not necessarily linked together in a straight peptide chain but are probably participants in a heterocyclic ring system. This could explain the formation of some intermediate hydrolysis products. Although I feel that the amino-acid sequence is not definitely established, there seems to be little doubt that the distribution of amino-acids in the bacitracin *A* molecule is highly asymmetrical. It is quite certain that the molecule consists of a lipophilic and a lipophobic part. Moreover, the uneven distribution of basic and acidic amino-acids makes the lipophilic part strongly polar. The antibiotic activity is probably primarily associated with the labile heterocyclic ring system and possibly with the *d*-amino-acids. Full biological potency may depend upon the asymmetrical shape of the molecule.

An Antifungal Substance from a Strain of *B. subtilis*

THOUGH a considerable literature has accumulated regarding the antibacterial action of *B. subtilis*, less attention has hitherto been paid to the antifungal action of the bacillus[1]. In the course of our investigation on the occurrence and isolation of antibiotic-producing micro-organisms from soil and infected foodstuff, an effort was made to collect different strains of the bacillus which would produce substances showing antifungal action especially against plant pathogenic fungi. The report of one such strain *B* (*X*) isolated from decomposed foodstuff and identified according to Bergey[2] is recorded here.

The bacillus was grown both in potato–peptone broth and yeast extract–sucrose broth at 30° C. for five days in shallow layers of 30 ml. in 500-ml. Erlenmeyer flasks. The culture filtrate was heated for 15 min. at 60°–70° C. The active principle was precipitated by acidification with dilute hydrochloric acid, or isolated more effectively by extracting the culture filtrate with *n*-butanol and evaporating the extract at 60°–70° C. *in vacuo*. The residue was repeatedly washed with water, the wash-liquor discarded, and the product was purified further by dissolving it in alcohol and reprecipitating with ether, when an orange-white precipitate was obtained. The solution was kept overnight at 4° C., centrifuged and the precipitate dried to give a dark-yellowish mass.

The substance was found to be insoluble in dilute hydrochloric acid but soluble in ethanol, butanol, dilute sodium hydroxide and 5 per cent sodium bicarbonate solution. It gave negative tests with Fehling's solution, 2,4-dinitrophenyl hydrazine and Ehrlich's reagent. No coloration was obtained with ferric chloride. The substance gave positive biuret and ninhydrin tests; Millon's reagent gave a faint pink coloration.

When kept at 4° C. the antibiotic retained its activity for more than three months. It was found to be stable when autoclaved at 120° C. for 10 min. but less so in alkaline solution. The antifungal action of the substance as determined by the agar cup and agar streak methods is shown in Table 1.

Table 1

Test organisms	Minimum inhibitory conc. (μgm./ml.)
1. *A. niger*	12·0
2. *P. notatum*	12–15·0
3. *A. oryzae*	20–25·0
4. *Alternaria solani*	25·0
5. *Pythium* sp.	200·0
6. *Fusarium* sp.	30·0
7. *B. cinerea*	15·0

It was also active against *Curvularia* sp., *Verticillium* sp., *Phoma* sp., *P. rotundum* and *Trichophyton* sp., but inactive against *Epidermophyton* sp. and *Microsporum* sp. at a concentration of 0·2 mgm./ml.

The substance was thus found to possess a broad antifungal spectrum, but little action was shown against the bacteria tested, namely, *Staph. aureus*, *E. coli*, *V. cholerae*, *K. pneumoniae*, *Eb. typhosa* and *Strept. haemolyticus*.

The antibiotic appeared to be homogeneous, as single spots moving near the solvent front were revealed on the paper chromatogram when tested with ninhydrin, and also microbiologically by using *n*-butanol – acetic acid – water or ethyl alcohol – water mixture (R_F about 0·67) as the developing solvent. The potentiometric titration of the substance with sodium hydroxide gave a *pK* of about 5·8.

Since the antibiotic was thought to be a polypeptide in nature, its acid-hydrolysate was subjected to both one- and two-dimensional paper chromatography[3] using phenol – water and benzyl alcohol – acetic acid – water (25 : 5 : 6·5) mixtures as solvents. The following amino-acids were revealed on the chromatogram: aspartic acid, glutamic acid, serine, threonine, alanine, tyrosine, *nor*valine, phenylalanine, and two unidentified spots near aspartic acid and phenylalanine respectively. The maximum intensity of the spot due to serine indicated predominance over the others. Glutamic acid was, however, found to be present in minute quantity.

The antibiotic was found to be strongly hæmolytic, and 50–100 mgm. of the substance per kgm. body-weight injected subcutaneously to mice was tolerated with difficulty. Further toxicity tests were not attempted in consideration of its strong hæmolytic action. The incorporation of 10 per cent horse serum in the assay medium partly diminished the activity of the substance against *A. niger*.

The substance differs from bacillomycin, mycosubtilin and fungistatin, which are known antifungal products of *B. subtilis*, in its antifungal and anti-bacterial activities. It appears to differ from bacillomycin by its very low content of glutamic acid, relative preponderance of serine and presence of a larger number of amino-acids in the acid-hydrolysate. It seems to resemble the incompletely characterized '*Aspergillus* factor' in its anti-microbial properties. Details of this work will be published elsewhere.

Fungistasis in Soils

THE work recently described by Dobbs and Hinson[1], suggesting the occurrence of a widespread fungistasis in soils, prompts us to describe certain observations we have made of a somewhat similar nature.

Soil water was displaced from several soils with alcohol. This was assayed for fungistatic activity by a serial dilution assay using *Botrytis allii*[2] as a test organism, which we have found more sensitive to antibiotics than most soil fungi. On several occasions growth was retarded in 1 : 2 and 1 : 4 dilutions, though germination was not inhibited; distortion of germ-tubes similar to that produced by griseofulvin[3] was sometimes seen.

'Cellophane' bags containing activated charcoal were buried at various locations and depths at Wareham Heath; after a period of 36 hr., these were dug up, the charcoal extracted with ether, the solvent evaporated and the residue dissolved in water. Fungistatic activity similar to that in displaced soil water was again observed on several occasions.

Slabs of water agar, or agar buffered at *p*H 7 with phosphate–citrate buffer, were placed in intimate contact with the face of sloping soil-profiles at Wareham Heath for about 36 hr. Within six hours of removal, these slabs were processed in one of two ways: either they were uniformly covered with a thin film of Czapek agar seeded with *B. allii* spores or strips or cylinders removed with a cork borer were placed on suitable agar plates seeded with *Bacterium coli*, *Bacillus subtilis* or *Botrytis allii*. The impression gained from several such experiments was that the agar slabs after exposure to the soil acquired localized areas of inhibitory activity, inhibition of all test organisms being observed at one time or another. The agar was in all cases contaminated with soil organisms; but the time during which these could have grown was not considered to be sufficient for them to have produced substances in the agar which could have caused the inhibitions seen, nor did the growth of contaminants coincide with the areas of inhibition.

None of these methods can be considered to be as sensitive as that of Dobbs and Hinson, since in each case some degree of dilution was involved and added nutrient was always present; but the traces of antibiotic activity detected were probably real and indicative of a more intense activity *in situ*. It is noteworthy, however, that our observations suggest discontinuous 'islands' of inhibition rather than a widespread 'sea' of inhibition. It is true, of course that the inhibition we have observed may be quite different in character and origin from that observed by Dobbs and Hinson.

A Rhesus Monkey with *B* Agglutinogen in the Erythrocytes

Previous studies on rhesus monkeys[1] showed that the serum contained an anti-*A* but no anti-*B* agglutinin; the erythrocytes, on the other hand, lacked the expected *B* agglutinogen. Group specific substance *B* could, however, be found in secretions and organ extracts[2].

I intended to demonstrate to my students this apparent deviation from the rule of reciprocal relationship between anti-*A* and anti-*B* agglutinins and *A* and *B* agglutinogens, when recently, through the kindness of Dr. S. L. Hora, director of the Zoological Survey of India, I was fortunate enough to get a sample of clotted blood from a female rhesus monkey (*M. mulatta*) about eight years old. The animal had been shot and the blood was taken from the heart immediately afterwards.

The serum was separated from the clot, centrifuged and inactivated. Tests with human blood cells of the four groups proved, as expected, the presence of anti-*A* in the monkey's serum.

The blood corpuscles, washed once, were suspended n normal saline to form a 2 per cent concentration. Tests were arranged first with ordinary human antisera of equal strength. Anti-*B* quickly produced a very strong agglutination, whereas anti-*A* only after about 15 min. resulted in forming a weak agglutinate.

In order to remove the heteroagglutinins for animal blood, purified agglutinin solutions were prepared according to the technique outlined by Wiener[3]. Again the rhesus blood cells were tested. Purified anti-*A* did not show any reaction, whereas with anti-*B* a clear strong clumping was obtained.

This result was unexpected. The possibility heoretically exists that a heteroagglutinin through non-specific absorption (*Sekundarbindung*[4]) to the B-beta complex might have been transferred to the purified anti-*B* solution. Therefore absorption experiments were carried out in order to verify the findings. Three drops of packed rhesus cells, washed once, were added to each 1 c.c. human anti-*A* and anti-*B* and left in the refrigerator overnight. The absorbed sera were then tested against known cell uspensions along with the unabsorbed sera as controls. The results are given in the accompanying able.

Serum	Test cells	Serum dilutions 1	2	4	8	16
Anti-*A* unabsorbed	*A*	+++	+++	++	+	–
,, absorbed with *rh*-cells	*A*	+++	++	++	+	–
Anti-*B* unabsorbed	*B*	+++	++	++	+	–
,, absorbed with *rh*-cells	*B*	±	–	–	–	–

Anti-*A* serum absorbed and unabsorbed both had a titre of 8. The absorption did not affect the strength of this agglutinin. Anti-*B* before absorption had also a titre of 8, but after absorption even in undiluted condition it was only strong enough to agglutinate partially the erythrocytes. The fluid between the very small clumps remained pink-coloured. Unfortunately, through an accident, no rhesus blood cells were left for checking if anti-*B* could be completely removed from the human serum.

The absorption tests thus confirm the results obtained with purified solutions. One could, however, assume that the anti-*B* serum used for the tests contained an unusually strong heteroagglutinin against rhesus blood, and further, that the reaction between heteroagglutinin and monkey cells through non-specific absorption simultaneously removed the anti-*B*. This argument can be rejected, as the titre of the serum was about the same for monkey and human cells. Non-specific absorption, if it occurs at all, causes only a small diminution in the titre of the heterologous agglutinin. The great difference in strength of absorbed and unabsorbed anti-*B* could thus not be the consequence of non-specific absorption. Moreover, for purified solutions and for absorption, different anti-*B* sera were used, and it is unlikely that both sera contained a similar unusually strong heteroagglutinin.

It may therefore be inferred from these facts that a rhesus monkey was found which possessed a *B* or a *B*-like agglutinogen in its erythrocytes.

First Record of the Rare Beaked Whale, *Mesoplodon europaeus*, Gervais, from the West Indies

On February 21, 1953, two small female whales came close inshore in Bull Bay, in the parish of St. Thomas, Jamaica, and were beached by local fishermen. I had the opportunity of examining them some eight and a half hours later, through the courtesy of Mr. A. Thomas, the Government fisheries officer. Preliminary investigation showed that they belonged to the group of beaked whales, and it was thought that they might be true two-toothed whales although the teeth were neither visible nor could they be felt through the gums. Upon removal of the flesh and examination of the skulls, the specimens were tentatively identified as *Mesoplodon europaeus*, Gervais, on the basis of the key to the species of *Mesoplodon* given by Raven[1]. Dr. Remington Kellogg of the Smithsonian Institution, U.S. National Museum, very kindly examined photographs of both the intact animals and the prepared skulls and confirmed this identification.

So far as I am aware, this capture marks the fifth and sixth specimens of *M. europaeus* to be recorded. The first and type specimen (described from the skull only) was found in the English Channel in 1840, the second on the coast of New Jersey in 1889, the third at Long Island in 1933, and the fourth at Middle Key, Florida, in 1935.

The larger of the two specimens was dissected on the beach, and the internarial epiglottis, the reproductive organs, portions of the kidney and certain glandular structures were removed and fixed. The mammary glands exuded milk when cut, and the uterus appeared to be in a semi-stretched condition, which suggested that this larger specimen was a lactating female which had given birth to a calf not many weeks previously. It may have been the mother of the younger specimen; but as very little is known of the reproductive habits of these forms, it is difficult to determine this with any certainty.

Careful dissection in the area surrounding the vent did not lead to the discovery of any pelvic bones; but it was noticed that a broad band of tough fibrous tissue was present in the region where one would normally expect to find the small pelvic bones. After being partially dissected, the specimens were removed to the Zoology Department of the University College of the West Indies, where the work of preparing and mounting is still being done.

A brief description therefore follows, and details of the osteology and certain soft parts will be described in a later paper when the skeletons are fully prepared.

Colour. Both animals were black dorsally, merging into a dark grey ventrally which had a pinkish tinge in it. A slightly lighter grey area in the region of the mammary folds corresponded with that described as whitish in Raven's specimen. The pectoral fins and tail flukes were all of a uniform black colour. A number of small light-coloured scarified areas were present, probably due to rolling in the surf over boulders in the process of beaching.

Form. The body contours followed very closely those described by Raven for his Long Island specimen; and in particular the exceptional width of the flukes was noted. The two long gular grooves of the larger whale were seen, a feature which Raven did not have an opportunity of noting in his specimen. The dorsal fin was set well back on the body.

Measurements. The external measurements of the larger specimen were as follows:

Tip of snout to notch of tail fluke	426·7 cm.
Tip of snout to posterior rim of blow hole	57 cm.
Tip of snout to eye	57 cm.
Tip of snout to posterior border of base of pectoral fin	119·4 cm.
Middle of dorsal fin to notch of tail fluke	165 cm.
Length of upper jaw from tip of snout to angle of mouth (over curves)	33 cm.

A detailed comparison of the skulls of the two Bull Bay specimens with those mentioned in Raven's paper shows that the larger of the two whales compares closely in proportions with the Long Island specimen, which is also a female and probably of approximately the same age. The smaller one is apparently much younger than the Atlantic City male whale—the skull being only 460 mm. in total length in comparison with the 675 mm. of the latter specimen. This small specimen therefore represents an earlier growth-stage and is the youngest *M. europaeus* to be recorded. As Raven points out, the tendency in Odontocetes is for the females to be larger than the males, and so the difference in age between the Atlantic City and the Bull Bay specimens is probably even greater than the measurements would at first sight suggest. The bones of the skull of the latter specimen are extremely fragile, some are incompletely ossified, especially in the rostral region, and the sutures are still widely open. As this calf is obviously not very old, it is tempting to speculat that the breeding ground of these whales may no be far away from the Caribbean.

An Aquatic Larva, suitable for Laboratory Work

THE larva of the caddis fly, *Setodes tineiform* Curtis (Trichoptera, Leptoceridae), has recently bee described by me[1] from material obtained from a larg artificial lake in Surrey. It was found to breed freel if the adults were confined to the top of an aquariu with muslin. It has an annual life-cycle and th larvae construct cases entirely of a labial secretic the size and appearance of a hedgehog quill.

The larva swims well, pulling its case behind, an the movement of the body can be watched throug the transparent case. It will remain alive for thr or four days packed in wet waterweed (not mos for postal transportation, or for two or three week with only sufficient water to cover in a Petri dish It requires only an abundance of any of the usu water weeds with their epiphytic algae for aeratio and food.

Occurrence of *Asparagopsis armata* Harv. o the Coast of Devon

RECORDS of the distribution of the red alg *Asparagopsis armata* Harv. have indicated a sprea of the species from the southern hemisphere. Th first collections in the northern hemisphere were Saint Eugène, Algeria, in 1923, and Guéthar France, in 1925[1]; the species was reported in Irelan in 1942[2]. The plant was first recognized on th coast of Britain in 1950, when Drew[3] found numerou specimens cast up on the beaches of the Lizar Peninsula, and in 1951 Horridge[4] reported attache specimens in the Scilly Isles.

In August and September 1953, specimens *Asparagopsis armata* were found at Wembury Beac and Bovisand Bay, South Devon; in both places th plants were attached, bore no reproductive orga and grew above mean low-tide level. The presen of *Asparagopsis* at these points indicates an eastwa spread of the species along the south coast of Britai

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, November 9

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. J. M. Houston: "Economic Development in French and Spanish Morocco".

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE, PHILOSOPHY OF SCIENCE GROUP (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. N. Tinbergen: "The Biological Study of Animal Behaviour: its Possibilities and its Limitations".

INSTITUTION OF ELECTRICAL ENGINEERS, EDUCATION DISCUSSION CIRCLE (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "What are the Requirements of Electrical Engineering Textbooks?"

Tuesday, November 10

INSTITUTION OF BRITISH AGRICULTURAL ENGINEERS (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 2.15 p.m.—Mr. Turner Cooper: "The Control and Removal of Surplus Water in the Soil".

INSTITUTION OF POST OFFICE ELECTRICAL ENGINEERS, LONDON CENTRE (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 5 p.m.—Mr. S. Welch: "The Influence of Signal Imitation on the Design of V.F. Signalling Systems".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

COMMUNICATION RESEARCH CENTRE (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. B. S. Haldane, F.R.S.: "Communication as a Biological Phenomenon"*.

SOCIETY OF CHEMICAL INDUSTRY, CHEMICAL ENGINEERING GROUP and OILS AND FATS GROUP (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. I. H. Chayen and Mr. D. R. Ashworth: "The Application of Impulse Rendering to the Animal Fat Industry".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. D. S. Berry: "The Stress Relaxation Method of Assessing Ageing Resistance".

ROYAL AERONAUTICAL SOCIETY (in the Library, 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. J. Taylor: "Gusts and their Measurement".

Tuesday, November 10—Wednesday, November 11

INSTITUTE OF PHYSICS, ELECTRON MICROSCOPY GROUP (at Birkbeck College, Malet Street, London, W.C.1)—Annual Conference.

Wednesday, November 11

ROYAL SANITARY INSTITUTE (at 90 Buckingham Palace Road, London, S.W.1), at 2.30 p.m.—Discussion on "Air Pollution and the London Fog of December, 1952", opened by Dr. E. T. Wilkins.

INSTITUTION OF ELECTRICAL ENGINEERS, RADIO SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. P. Fairbairn: "Some Aspects of the Design of V.H.F. Mobile Radio Systems".

BRITISH INSTITUTION OF RADIO ENGINEERS, LONDON SECTION (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6.30 p.m.—Mr. J. W. Jenkins, Mr. J. H. Evans, Mr. G. A. G. Wallace and Mr. D. Chambers: "A High-Definition General Purpose Radar".

OVERSEAS SCIENCE STUDENTS ASSOCIATION (at the Society for Visiting Scientists, 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Sir Alexander Fleming, F.R.S.: "The Search for Antibiotics".

BRITISH SOCIOLOGICAL ASSOCIATION (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 8 p.m.—Mr. R. B. Buzzard: "Attendance and Absence in Industry".

Thursday, November 12

PHYSICAL SOCIETY, OPTICAL GROUP (at the Institute of Ophthalmology, Judd Street, London, W.C.1), at 2.30 p.m.—Dr. G. B. Arden and Dr. R. A. Weale: "The Latent Period of Vision and the Pulfrich Effect".

EAST MALLING RESEARCH STATION (at Withersdane, Wye College, near Ashford, Kent), at 4 p.m.—Prof. R. H. Stoughton: "Some Aspects of the Growth and Development of Fruit Plants"* (Amos Memorial Lecture)

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. A. H. Wilson, F.R.S.: "The Research Department of Courtaulds Limited"

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Safety Precautions in Electronic Apparatus, with Particular Reference to Medical Applications".

ROYAL AERONAUTICAL SOCIETY (at the Institution of Mechanical Engineers, Storey's Gate, London, S.W.1), at 6 p.m.—Mr. J. G. Vinpenny: "Stability and Control in Aircraft Design".

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (at the Medical Society of London, 11 Chandos Street, Cavendish Square, London, W.1), at 6.15 p.m.—Dr. J. G. Davis: "The Microbiology of Different Types of Cheese".

Friday, November 13

SOCIETY OF CHEMICAL INDUSTRY, CORROSION GROUP (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 9.45 a.m.—Symposium on "Cathodic Protection".

ASSOCIATION OF APPLIED BIOLOGISTS (in the Physics Laboratory Building, Royal Fort, University of Bristol, Bristol), at 11 a.m.—Scientific Papers.

POSTGRADUATE MEDICAL SCHOOL OF LONDON (at Ducane Road, Shepherd's Bush, London, W.12), at 4 p.m.—Dr. L. G. Pugh: "The 1953 Everest Expedition".

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

BEDSON CLUB (in Lecture Theatre II, The Chemical Laboratories, King's College, Newcastle-upon-Tyne 1), at 5.30 p.m.—Dr. A. F. Wells: "The Third Dimension on Chemistry".

NORTH EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (in the Lecture Theatre of the Mining Institute, Neville Hall, Newcastle-upon-Tyne), at 6.15 p.m.—Prof. L. C. Burrill and Mr. Arnold Emerson: "Propeller Cavitation: Some Observations from 16-in. Propeller Tests in the New King's College Cavitation Tunnel".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. K. A. G. Mendelssohn, F.R.S.: "A New State of Aggregation".

Saturday, November 14

BIOCHEMICAL SOCIETY (in the Department of Biochemistry, St. Mary's Hospital Medical School, Paddington, London, W.2), at 11.30 a.m.—Scientific Papers.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SCIENTIST, Grade 3 (with good honours degree in science (physics or chemistry)), IN THE DUST SUPPRESSION SECTION of the Divisional Scientific Department, National Coal Board—Divisional Chief Scientist, National Coal Board, Northern (N. and C.) Division, The Grange, Grange Avenue, Longbenton, Newcastle-upon-Tyne (November 7).

RESEARCH ASSISTANT (with first- or second-class degree in physiology, biochemistry or chemistry, or A.R.I.C.) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY of the United Bristol Hospitals—The Secretary to the Board, Royal Infirmary Branch, Bristol 2 (November 14).

SENIOR PHYSICIST (with honours degree or equivalent, and at least five years experience in the gas or chemical industries) with the West Midlands Gas Board, Area Laboratories, Birmingham, for duties including physical determinations and investigations, and the supervision of such work—The Industrial Relations Officer, West Midlands Gas Board, 6 Augustus Road, Edgbaston, Birmingham 15 (November 14).

ASSISTANT, Grade B (with good academic qualifications and experience in physical chemistry), IN CHEMISTRY—The Clerk to the Governors, Chelsea Polytechnic, Manresa Road, London, S.W.3 (November 16).

DEMONSTRATOR (honours graduate in chemistry or biochemistry) IN CHEMICAL PATHOLOGY—The Registrar, The University, Leeds (November 16).

DEMONSTRATOR IN AGRICULTURAL CHEMISTRY—The Registrar, The University, Leeds 2 (November 16).

LABORATORY TECHNICIAN (preferably with experience in biophysical or physical-chemical laboratories) to work with the electron microscope and ultracentrifuge—The Secretary, The Foot-and-Mouth Disease Research Institute, Pirbright, Surrey (November 16).

SENIOR LECTURER or LECTURER IN BOTANY, and a LECTURER IN GEOGRAPHY, at the Nigerian College of Arts, Science and Technology—The Secretary, Advisory Committee on Colonial Colleges, 1 Gordon Square, London, W.C.1 (November 16).

LECTURER or ASSISTANT LECTURER (with good degree in mining and preferably a first-class certificate of competency) IN MINING, and a RESEARCH ASSISTANT (with good degree in mining engineering or pure science) TO THE PROFESSOR OF MINING—The Registrar, The University, Sheffield (November 20).

ASSISTANT LECTURERS (2) (one with special qualifications in horticulture, and the other with a special interest in biochemistry) IN BOTANY—The Registrar, The University, Manchester 13 (November 21).

ASSISTANT PHYSICIST (with honours degree in physics, and preferably with experience in research work) at Saint Luke's Hospital, Dublin—The Secretary, The Cancer Association of Ireland, "Oakland", Highfield Road, Rathgar, Dublin, quoting "A.P." (November 21).

CHEMIST (with H.S.C. (science) or equivalent, but degree or H.N.C. in chemistry may be an advantage) at the Royal Ordnance Factory, Blackburn, to supervise staff engaged on chemical and physical analysis of materials and some mechanical testing—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.514/53A (November 21).

ASSISTANT LECTURER IN PHYSICS—The Registrar, Queen Mary College, Mile End Road, London, E.1 (November 27).

ASSISTANT LECTURER IN PHYSICS—The Secretary, Birkbeck College, Malet Street, London, W.C.1 (November 28).

SCIENTISTS and ENGINEERS (with degree or equivalent in science or engineering) in the Scientific Department of the National Coal Board to carry out environmental studies at Collieries in connexion with a long term field research into the occurrence and causes of pneumoconiosis—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/700 (November 28).

LECTURER (with special interest in organic chemistry) IN CHEMISTRY—The Secretary of University Court, The University, St. Andrews (November 30).

LECTURER IN ELECTRICAL ENGINEERING—The Registrar, The University, Manchester 13 (November 30).

LECTURER or ASSISTANT LECTURER IN CIVIL ENGINEERING at the University College, Khartoum, Sudan—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (November 30).

Scientific Officer or a Senior Scientific Officer (with good honours degree in biochemistry, or registered veterinary surgeon, and preferably with research experience in the metabolism of farm animals) in the Biochemistry Department—The Secretary, Moredun Institute, Gilmerton, Edinburgh 9 (November 30).

Chair of Organic Chemistry—The Secretary, Queen's University, Belfast (December 3)

Lecturer or Senior Lecturer in Zootechny at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Sydney, December 5).

Chair of Organic Chemistry tenable at King's College, Newcastle-upon-Tyne—The Registrar, University Office, 36 North Bailey, Durham (December 7).

Dairy Officer (with degree in dairying, and preferably with experience in pasteurization of milk, and knowledge of cream grading for butter manufacture) in the Department of Agriculture, Southern Rhodesia Government—The Secretary, Rhodesia House, 429 Strand, London, W.C.2 (December 15).

Lecturer in Geography (Grade 1), and a Lecturer in Mathematics (Grade I) at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth 5, Gordon Square, London, W.C.1 (December 15).

Lecturer in Geography—The Secretary, The University, Aberdeen (December 30).

Professor of Textile Chemistry—The Registrar, College of Technology, Manchester (December 31).

Huntley and Palmers Agricultural Research Fellowship, for independent research in some branch of agriculture, dairying or horticulture, or the sciences related thereto—The Registrar, The University, Reading (January 23).

Reader in Pathology at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Adelaide, January 31).

Assistant Engineers (with recognized university degree or diploma in civil engineering carrying exemption from Sections I and II of the A.M.I.C.E. examinations, and with at least two years approved practical experience, or A.M.I.C.E.) in the Public Works Department, Tanganyika—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE 112/8/03.

Assistant, Grade A (with university degree in science, and prepared to teach two or more of the following: botany, zoology, chemistry and general food science to Inter.B.Sc. standard) in the Department of Food Technology—The Principal, Borough Polytechnic, Borough Road, London, S.E.1.

Assistant Lecturer in Agricultural Zoology—The Bursar, Royal Agricultural College, Cirencester.

Director (with first- or second-class honours degree in a pure science, and with considerable postgraduate experience in microbiological research) of the Colonial Microbiological Research Institute, Trinidad—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.87/38/01.

Hydraulic Engineers (with university degree or diploma in civil engineering carrying exemption from Sections I and II of the Institution of Civil Engineers' examinations, or be A.M.I.C.E.) in the Public Works Department, Kenya, for duties which will include investigation, design, construction and maintenance of township water supplies, development of rural water supplies and water conservation—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.112/7/02.

Lecturer (with good honours degree in mining engineering and a wide knowledge of mine ventilation and fluid mechanics) in Mining Engineering—The Registrar, The University, Nottingham.

Physicist or Organic Chemist (with research experience, and preferably with some knowledge of X-ray crystallography and/or coal or carbon research) for fundamental research on chemical and physical aspects of carbonization—The Clerk, Birkbeck College, Malet Street, London, W.C.1.

Physicists (recent graduates, with Ph.D. or equivalent) for work on electronics or physical measurements; Metallurgists (recent graduates, with Ph.D. or equivalent) for investigating fatigue failures, and other problems associated with the metal-working industries; and an Electronics Technician to take charge of the instrumentation in connexion with problems in physics, chemistry and biology—Dr. G. M. Shrum, Director, British Columbia Research Council, Vancouver 8, Canada

Research Assistant in the field of physical chemistry (reaction kinetics)—The Registrar, University College, Exeter.

Research Fellow or Research Student (preferably with knowledge of electronics) for fundamental investigations of semi-conductors—The Registrar, The University, Nottingham.

Research Officer (with at least good second-class honours degree in botany, with training in genetics, and at least two years postgraduate experience in plant breeding, preferably in cereals) with the Maize Rust Research Scheme, Nigeria—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting 27059/320.

Scientific Officer (with first- or second-class honours degree in inorganic or physical chemistry) at the National Physical Laboratory, Teddington, for research on analytical techniques in metallurgy—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.525/53A.

Scientific Officer (with first- or second-class honours degree or equivalent in engineering, physics or mathematics, and good working knowledge of aerodynamics and/or engineering practice) in the Ministry of Supply, London Headquarters, to assist in administration of aerodynamic research programme, mainly concerned with rotating wings, and to contribute to initiation of new items of research and analysis of new projects—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1 quoting C.571/53A.

Senior Research Entomologist to take charge of research on cotton pests, at the Empire Cotton Growing Corporation's research station, near Kampala, Uganda—The Secretary, Empire Cotton Growing Corporation, 12 Chantrey House, Eccleston Street, London, S.W.1.

Senior Scientific Officer or Scientific Officer (with veterinary qualifications registrable in the United Kingdom, and basic training in hæmatology, pathology, chemotherapy and the principles of immunology, and in the case of Senior Scientific Officer at least three years postgraduate experience) to undertake duties of Veterinary Research Officer in the West African Institute for Trypanosomiasis Research—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.67/39/01.

INDUSTRIAL EFFICIENCY AND SCIENTIFIC RESEARCH

IN opening the discussion on training for management at the British Association meeting at Liverpool, Prof. R. S. Edwards made the suggestion that Counterpart Funds derived from United States Economic Aid might be used for encouraging industrial support of postgraduate training in management by providing half the salaries of industrial candidates accepted for such courses. Behind such proposals lies the belief that the technical backwardness of sections of British industry and their failure to exploit the results of scientific research are due to deficiencies in management, either through failure to employ sufficiently trained men as managers, or through insufficient representation in management of men with a strong scientific or technical background. The Select Committee on Estimates in its recent inquiry into technical education noted the unanimity of view as to the vital importance of technical and commercial education to Britain's competitive power in world markets and the higher productivity of her industries.

Nevertheless, the proposal to use Counterpart Funds (see *Nature*, Sept. 19, p. 528) in this way to increase productivity is not one to be endorsed without careful consideration, particularly in the light of the last report of the Advisory Council on Scientific Policy, and of Mr. Graham Hutton's examination of the effect in their own industries of reports of the returning members of sixty-one productivity teams from British industry which the Anglo-American Productivity Council sent to the United States. Questions much more important than the best means of training managers are involved, and no appreciation for the generosity and altruism of the United States should be allowed to stand in the way of a critical inquiry which bears closely on the health of British industry as a whole. Moreover, not merely the application of the results of research but also the initiation and organization of research appeared to be involved and certain aspects of the relations between industry and the universities.

Mr. Graham Hutton's book, published under the title "We Too Can Prosper: The Promise of Productivity" (pp. 248; London: Allen and Unwin, Ltd., 1953; 12*s*. net), assesses the findings of the teams in the light of information and advice from the Anglo-American Productivity Council and in collaboration with Mr. Geoffrey Crowther, editor of *The Economist*. In spite of the unanimous conclusion of all the teams that a higher output could be obtained in Britain without increasing strain or stress on operatives and with a modest re-equipment programme, mainly by better managerial and trade union methods, the book holds out little hope that the advice of the productivity teams will accelerate the process. Some of the improvements which could quickly increase productivity are simple and homely: Mr. Hutton estimates that re-organization of work alone could achieve a 10 per cent increase in productivity. Such reorganization, however, has to overcome the inertia and conservation of both management and trade unions and other obstacles inherent in an old industrial system.

The obstacles to better utilization of work are in fact largely psychological and human; but while Mr. Hutton's book may reach a wider public, we must review any proposals to increase productivity and secure the more effective utilization of the results of research and of physical effort in the light of such an attitude. Failure to deal with the root causes of such a climate of opinion can only result in continued frustration and in the waste of resources that could with advantage have been deployed to remove the real obstacles. Imagination and understanding of the human issues are probably the first essentials in arriving at a decision as to the right policy, and that is as true of both sides of industry as it is of government.

The projects for which grants from Counterpart Funds have been proposed cover an extremely wide field. Some are frankly debatable, and, on the face of it, are for things that British industry should be well able to do for itself. Others would seem to be well within our capacity to support if there was only the will to devote resources to the purpose, even if it involved the diversion of resources from some other less essential purpose.

This is the fundamental reason for hesitation in welcoming the proposals of the White Paper for the use of Counterpart Funds. The Select Committee on Estimates, in two reports issued last summer, made it clear that the nation has yet to face frankly and realistically its educational aims and programmes in terms of the resources allocated or available. Neither major political party has yet indicated that it is prepared either to adjust the aims and programme or the resources to be allotted for educational purposes, still less to indicate where else it would make savings in national expenditure to supply the finance or materials. The same position arises in regard to research expenditure, and it has been pointed out in these columns that mere prunings may be quite inadequate to provide for any further increase in national expenditure on scientific and industrial research, however essential. It is probable that that expenditure can only be maintained at an adequate level by reduction of expenditure in other sectors, like the social services, where it is highest.

The danger is thus that these proposals for the use of Counterpart Funds may merely postpone an inevitable choice and, in postponing, make a reasonable—if unpleasant—decision even more difficult. Moreover, in themselves, it is arguable that some of the suggestions are damaging to British self-respect and self-reliance. Almost half a million pounds is to be spent on advisory services which will bring to the notice of individual firms improvements in modern technique. Of this, £150,000 will be spent through the Department of Scientific and Industrial Research broadly in implementing the policy of securing the more effective utilization of the results of research on which both the Advisory Council for Scientific and Industrial Research and the Advisory Council on Scientific Policy laid stress in recent reports. Some of it, however, goes to trade and industrial associations which exist to perform such services, primarily for their individual members. Whether or not it i right to subsidize such services in this way, doubts may be entertained as to the efficacy of such expenditure: a high return in terms of public advantage is unlikely.

Such expenditure through the Department o Scientific and Industrial Research may do no more harm than enable the Government to delay decisions for which the Advisory Council has pressed hard but fruitlessly in at least two successive reports. The objection could equally be brought against the sum of just under £600,000 provisionally allocated fo research. The usual objections to sponsored research cannot well be made here: the specific studies fo which grants are proposed are based, so far a economic research is concerned, on proposals already advanced by universities and research organizations Those contemplated in social research are to b planned and co-ordinated by the two Committee on Human Relations in Industry and on Industrial Efficiency in Industry recently set up by the Lor President of the Council to advise the Department of Scientific and Industrial Research and the Medical Research Council. In both fields the detailed research projects are to be defined in discussions with th universities and the research institutes.

It can, of course, be urged that the results of such research will be published and made fully availabl in the United States and elsewhere as well as in Great Britain. That could also apply to the programme of research on innovation and the development of new ideas, the flow of scientific and technical information to industry and its relation to innovation and industrial efficiency, on the economics of re equipment and on the measurement of productivity and the causes of variation of industrial efficiency for which £75,000 has been set aside. Indeed, industry in other countries may once again prove quicker t apply whatever is of value in the results of such research than British industry. Moreover, it is possible that one factor in the slowness of som sectors of British industry in applying the result of fundamental research is that those sectors hav borne no direct responsibility for the financial support of such research.

If this is true, doubts as to whether the proposals in the White Paper represent the right means fo increasing our investment in research are likely t grow; nor is it wise to assume without closer inquir that the half-million pounds provisionally allocated for education and training is the most appropriat means for endowing chairs or readerships in th universities or for creating teaching posts in industrial engineering at technical colleges. The provision made for postgraduate scholarships and other scholarship in this way is scarcely open to question; but th procedure is at variance with the universities' well-known objections to ear-marked grants. In view c the recommendation in the last report from the University Grants Committee that the system c ear-marked grants should now be discontinued, it is interesting to note that while the University Grants

Committee was consulted in drawing up the industrial section of the programme, there is no indication that it was also consulted in framing the proposals for expenditure on education and training.

The White Paper states that the projects selected for grant were chosen "as being likely to contribute to the development of the national economy by reason of the industry or field of studies to which they were related and the probable effectiveness of the programme of work suggested, and as not being likely to cause a continuing burden on the Exchequer at the end of the programme". This is probably the most important sentence in the White Paper, and since for the reasons given above it is doubtful whether the most effective means have been chosen for achieving the declared objectives, the Government incurs at least the suspicion that the real reason for the proposals lies in the final words. They are an attempt to expand research and training, without the clear thinking and hard decisions which must accompany any real attempt to allocate further national resources to the universities and other institutions for higher education and research, and to the Department of Scientific and Industrial Research.

Such suspicions would be less reasonable if the Government had given any real signs of having a definite policy so far as either education or research is concerned, or if either major political party had indicated a readiness to face the facts of the situation. While, however, political parties refuse to recognize that the allocation of adequate resources to either education or research is likely to involve increasingly the curtailment of national expenditure on other social services or inroads on the standard of living, at least until the international situation and the economic position of Britain permit some reduction of expenditure on defence and of export priorities, it is unlikely that a considered policy in respect of education or research will be evolved. The frustration and waste to which the reports of the Select Committee on Estimates and the recent reports of the Department of Scientific and Industrial Research have borne witness are likely to continue.

The generosity of the United States should be unhesitatingly acknowledged and welcomed; but reservations must be made as to the wisdom of the Government's proposals to ear-mark the funds in the way indicated. For the reasons given, it might well be wiser for the Government, in accepting the aid, part of which is allotted conditionally for "purposes intended to encourage a healthy and expanding economy by promoting the productivity of industry and by stimulating competition", to have devoted it to such purposes generally rather than specifically, and in ways that were less open to suggestions either of 'easy money' or of evasion of constructive thought. In terms of the current expenditure of Great Britain on university, technological and technical education and on scientific research at the universities and in government and independent institutions, £3,000,000 is not an excessive sum, and under wise direction could do much good. It is large enough, however, to cause distortion and to do harm without such direction, and the implications of the whole situation merit examination both by the Advisory Council on Scientific Policy and by the Parliamentary and Scientific Committee.

The latter body could possibly do something to initiate the all-party approach to the question of the national investment in research and education which may well be essential before either political party can be expected to adopt measures so unpopular as the curtailment of expenditure on social services in the absence of an attempt to explain its reason and necessity. Agreement on that step would still leave room for difference of opinion as to the allocation of resources on different levels of education or in different fields of research; but it should also help to remove such irrationalities as that seen at the Trade Unions Congress in the dissatisfaction that the widening of the opportunities for university education, by drawing off more of the abler school-leavers, has diminished the prospects of promotion to managerial levels from the shop or factory floor.

The last report of the Advisory Council on Scientific Policy was specifically concerned with investment in research, and suggested that a significant increase in the volume of such investment is the most effective single measure that could conduce to a greater exploitation of science by industry; nevertheless, the Advisory Council was equally aware that an increased investment in technological education, if not also in the science departments of the universities, could also assist. While recognizing that it is particularly an increase in the amount of risk capital that is required, the Advisory Council, like the Government in framing the programme for the expenditure of Counterpart Funds, gave scarcely enough attention to the means proposed for achieving its ends. The Advisory Council did not accept the usual argument that current rates of taxation directly discourage expenditure on research and development, though it admitted that a major improvement in investment cannot be expected without a big change in Government policy. In relying on institutional research and investment and such means as the National Research Development Corporation to bring about a radical improvement in British industry, the Advisory Council appeared to lose sight of the essential factor, just as does the White Paper on Counterpart Funds.

The real problem is to create in industry the receptivity to new ideas and the readiness to experiment and to take risks, both in research and in development. That cannot be done by transferring to government departments or like institutions the responsibility for identifying technical needs and taking the risks involved in promoting technical development; Sir Henry Tizard made that very clear in his Messel Memorial Lecture last year. The Advisory Council's proposals, like those for the use of Counterpart Funds, do nothing to decrease the tendency for some sectors of British industry to continue to leave most of the risk to be borne by the Government.

More co-operation between industry and the Government in development may be required through such devices as the research associations and the

National Research Development Corporation; but the responsibility for enterprise and adventure should rest, by and large, on industry. As Prof. R. S. Edwards, like the Advisory Council, pointed out in an earlier article on industrial research and development in Great Britain, the Government's primary responsibility is a negative one, namely, to see that our economic arrangements and the level and incidence of taxation do not weight the scales too heavily against the supply of capital for risk-bearing ventures. On the positive side, the Government's task is also to see that neither whole industries nor individual firms are shielded by restrictive agreements or associations from the consequences of lack of enterprise and failure to utilize new knowledge, and that full opportunity and encouragement is given to those willing to enter and venture on these fields. A prime task of government should, in fact, be to secure the mobility that industrial development demands. The defects of British industry largely flow from its excessive rigidity and the increasing extent to which units and individuals are screened from the consequences of their own mistakes or inertia. In post-war Britain, the concern to mitigate the consequences of technological change and development tends not so much to the science of social adjustment advocated by Lord Stamp as to discouragement of development generally. Not merely the pattern of nationalization, but also the general climate of opinion in wide sectors of society, are averse to change and all that is implied by the developments required to safeguard Britain's economic future.

There is, of course, much room for constructive thought regarding the whole organization of research and development in Great Britain. Prof. Edwards's suggestions for association of the universities, the colleges of technology and the research associations in meeting the increased demand for sponsored research merit examination, giving due weight to the dangers and difficulties to which Sir John Stopford and others have directed attention. The same institutions and government research establishments have also a contribution to make to higher technological education and the supply of managers as well as technologists, and the possibilities of co-operation are far wider than was indicated in the British Association discussion at Liverpool. American experience may have something to teach us in both respects, and the inquiries recently conducted by the National Science Foundation into the use of Federal funds in support of research and development have a close bearing on evolution of a policy in Great Britain also.

The report of the Advisory Council on Scientific Policy and the White Paper on the use of Counterpart Funds would be less disturbing if there were any evidence that the Government has a policy for research and development. All the evidence at present suggests that such issues are evaded, and that science is treated with less and less respect in the counsels of the State. The task of securing the adequate use of science by industry in Great Britain has not been seriously considered by the Government during the past four or five years. The first step is that of encouraging fluidity, of making industry less rigid and more open to pressure to seek and use new knowledge. The prime responsibility rests with the Government, though it will still remain for industry to show that it possesses the determination, enterprise, courage and imagination to use opportunities which may be afforded. That again is partly a matter of industrial recruitment, and here government policy in the allocation of resources for university and technological education is an essential factor in securing an appropriate flow of trained man-power. Finally, on government policy depends the wise deployment of our resources in material, finance and man-power between government organizations, the universities and other independent research institutions, and industry itself, so that the national effort is in balance. Not only is such a balance necessary, but also conditions must be such that they attract a sufficient number of the nation's most creative minds, and allow them to work under the most fruitful conditions; thus implementing, so far as possible, the application of the new knowledge wherever it is required, in industry or in the service of the national welfare.

COMPARATIVE ANATOMY AND TAXONOMY OF THE LEMURS AND LORISES

Primates

Comparative Anatomy and Taxonomy. 1: Strepsirhini. By Dr. W. C. Osman Hill. (Edinburgh University Publications, Science and Mathematics No. 3.) Pp. xxiii+798+24 plates. (Edinburgh: At the University Press, 1953.) 105s. net.

DR. W. C. OSMAN HILL has undertaken the considerable task of assembling in a work of reference "the more scientific aspects" of what is known about lemurs, monkeys and apes. Vol. 1, which is the volume under review, deals with the lemurs and opens with a general section on the diagnostic characters and classification of the whole order of Primates. Like most contemporary students, Dr. Hill accepts the definition of a Primate laid down by St. George Mivart in 1873 but, in addition, provides information about other general characteristics (for example, placentation, physiology of reproduction, dentition). Then follows an account of the geological and geographical distribution of the Primates, and of their taxonomy and phylogeny. No new ground is broken; but Dr. Hill does not accept Gaylord Simpson's recent proposal to subdivide the order into the two sub-orders Prosimii and Anthropoidea, and to include in the former the Tupaiidae and Tarsioidea. Instead, he reaffirms Pocock's previous subdivision of the Primates, from which he completely excludes the Tupaiidae, into the two "grades", Strepsirhini (lemurs and lorises) and Haplorhini (essentially monkeys and apes), and classifies the Tarsioidea as a sub-order of the Haplorhini, rather than with the Strepsirhini.

A general introduction to the Strepsirhini then follows. It begins with a list of the lemurs and lorises, and goes on to a fairly detailed and systematic account of their general anatomy. Information is also provided about gestation, placentation and development. The natural behaviour of lemurs and lorises is discussed, and a special section deals with what Dr. Hill calls "Mental Development".

The next hundred and fifty pages of the book are devoted to the sub-order Lorisoidea of the Strepsirhini, consisting of the two families Lorisidae and Galagidae. The sub-order Lemuroidea, with its eight constituent families, takes up the five hundred pages which follow. The same pattern of treatment is followed throughout. Thus, a general section defines the external characters, the systematic anatomy, the development, the behaviour and the taxonomy of the whole sub-order of Lorisoidea; more specialized sections are devoted to its two families; still more specialized sections deal with each of their constituent genera; and these in turn are followed by sections describing each species. Interesting historical data are also provided. While the amount of detail within each section varies with our knowledge and ignorance, the pattern of treatment which Dr. Hill has followed necessarily results in some repetition.

The whole text is generously illustrated with line-cuts and half-tones. There are thirty-four plates, about half of which illustrate living animals. Useful maps are provided to show the distribution of the various species, and there is a sixteen-page list of references and an index.

The preparation of the book must have demanded enormous enthusiasm and endless patience, and there can be no question that Dr. Hill has rendered a service to his fellow-students of the Primates. The volume is, however, uneven, not only because of gaps in our knowledge, but also because Dr. Hill seems less at home in some sections of his book than he is in those which deal specifically with anatomical and taxonomic matters. In the latter he has incorporated most of what other workers have published, including descriptions of the bones and dentition of fossil lemurs. His own contributions have been mainly concerned with the taxonomy and external characters of living Primates, especially of their external genitalia, and it is understandable that considerable space, and a very disproportionate number of the illustrations, are devoted to the latter topic. But this is at the expense of what many workers might regard as more important issues (for example, the skeleton, muscles, nervous system, etc.). The sections dealing with "the scientific aspects of primate behaviour", including the few called "Mental Development", show that we still know very little about the lives and behaviour of lemurs and lorises.

How much of the information that is given about the history of our knowledge of lemurs and lorises is the fruit of original historical research is difficult to judge. Some clearly is, but some is obviously not. For example, Dr. Hill tells us that Madagascar, the home of the lemurs, was well known to the Ancients, and that it was known to the Greek geographer "Ptolemy, (third century B.C.)" . . . under the name Menuthias. There appears to be at least two errors here[1]: the period of Ptolemy, the geographer, was the middle of the second century A.D., not the third century B.C.; and the name Menuthias, which first appears in the Periplus, an anonymous work of the first century A.D., relates to the coastal islands of Zanzibar or Pemba. Several decades later, Ptolemy correctly noted that Menuthias lay near the coast, but his figures for latitude and longitude wrongly placed it far out to sea. Hence the subsequent confusion of Menuthias with Madagascar.

In the area covered by the book, one man's fact is not infrequently another's bone of contention, and Dr. Hill does not entirely succeed in his avowed purpose of avoiding discussions of a controversial nature. To take one example, he scarcely begins to justify the case for excluding the Tupaiidae from the taxonomic relationship with the Lemuroidea which has been argued by such workers as Kaudern and Le Gros Clark, and which Simpson recognizes in his classification. Another debatable point is the statement that the way in which the menstrual cycle, which is a primate characteristic, is differentiated from the oestrous cycle of the non-primate mammal is that in the latter uterine bleeding occurs at the time of ovulation, whereas bleeding in the menstrual cycle occurs at the end of the luteal phase. In point of fact, uterine degeneration associated with bleeding is the exception rather than the rule in the oestrous cycle of non-primate mammals.

There are, unfortunately, other examples of debatable statement. Thus, considerable space is given to a description of the genitalia of the common brown lemur, *L. fulvus*, and of the mongoose lemur, *L. mongoz*, Dr. Hill writing that "there is no sexual attraction between females of the latter species and males of the former" and that the two species are "probably incompatible". He also states that "the differences in the sexual organs are probably to be attributed to divergent evolutionary trends based upon their incompatibility". Whatever is meant by this last sentence, it is on record that hybrids between the two species have occurred. Dr. Hill also speculates, without data, about the periodicity of breeding in the Lemuridae and Galagidae, but dismisses actual records which are contrary to his beliefs. He writes, too, that the breeding season of lemurs is the same in captive as in wild specimens, and that it is not affected by environmental changes. But there are indications that lemurs, like practically all other mammals from the southern hemisphere, switch their breeding seasons when moved to captivity in the northern hemisphere. If this were not so, they would be very exceptional mammals. Dr. Hill also refers to the existence of a sexual skin in the Strepsirhini, without giving any more basis for this belief than he does for his description of the spleen as one of the ductless glands.

Nevertheless, he has provided a book which students of the Primates, both to-day and to-morrow, are certain to consult before they undertake any researches on lemurs. One can only regret, therefore, that all its contents do not sustain the scholarly impression which the book first gives. Readers will particularly regret the frequent omission of the names of the authorities on which various statements are based; for a work of reference fails in a major purpose when those who use it cannot bring their own critical powers to bear on the sources of particular pieces of information it incorporates.

Obviously these shortcomings are an indication of the very exacting task which Dr. Hill has tried to fulfil. He has undoubtedly done much better than did D. G. Elliott in the much criticized three-volume "Review of the Primates" which was published in 1913, and which Dr. Hill's new work supersedes. But some readers may well consider that Dr. Hill could have served his fellow students better if, in addition to his taxonomy, he had devoted the bulk of his attention to a detailed account of the structural anatomy of, say, a member of each of the families of the Lorisidae and Lemuridae rather than spread himself thinly over the whole field. It is to be hoped that any subsequent volumes on the Primates which Dr. Hill may produce will improve on, as well as perpetuate the good points of, the present volume.

POLYCYCLIC NITROGEN HETEROCYCLES

Heterocyclic Compounds

Edited by Robert C. Elderfield. Vol. 3: Polycyclic Derivatives of Pyrrole; Polycyclic Systems with One Nitrogen Common to Both Rings; Pyrindine and related Compounds. Pp. vii+442. 96s. net. Vol. 4: Quinoline, Isoquinoline and their Benzo Derivatives. Pp. vii+674. 136s. net. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.)

THE ambitious scheme to produce a modern treatise on the chemistry of heterocyclic compounds has made considerable headway with the appearance of these two volumes. They will probably have an even wider appeal than Vols. 1 and 2 (see *Nature*, 168, 618; 1951), for as Prof. R. C. Elderfield says in his preface to Vol. 3, "the chemistry of the polycyclic nitrogen heterocycles containing one hetero nitrogen atom has probably been the object of more intense investigation than any other single group in the broad field of heterocyclic chemistry". It is with these polycyclic nitrogen compounds that Vols. 3 and 4 are concerned. The major part of Vol. 3 (274 pages) is devoted to a most timely and interesting chapter on indole and its derivatives by P. L. Julian and two collaborators. Prof. Elderfield's contribution is far from being restricted to editorial duties. He has himself written the 343-page chapter on quinoline (Vol. 4), and is part author of the chapters on *iso*indole and on pyrindine, quinindine and their derivatives (Vol. 3). A chapter by H. R. Ing on bicyclic systems with a nitrogen atom common to both rings completes Vol. 3, and Vol. 4 contains also chapters on *iso*quinoline (Walter J. Gensler), the acridines (Adrien Albert), and phenanthridine and benzoquinolines (L. P. Walls). The names of the authors are a sufficient assurance of the authoritative character of the work. So vast a field of organic chemistry as heterocyclic compounds can be surveyed with authority only by a multiplicity of authors, and it is inevitable, therefore, that there should be a certain lack of uniformity in treatment.

Comprehensiveness is not claimed. In particular, there is no detailed treatment of the considerable groups of alkaloids which are derived from the ring systems dealt with in the volumes under review. This omission is entirely justifiable. There are other excellent modern works dealing with alkaloids, and their inclusion in the present work would have made it unwieldy, besides unduly delaying its progress. Although alkaloids are not dealt with systematically, there is incidental reference to many of them; for example, in connexion with quinuclidine, pyrrocoline and pyridocoline, *iso*quinoline and phenanthridine.

The chapter on indoles gives a survey of numerous methods for their synthesis and a discussion of the mechanism of some of the reactions involved. There is a description of the preparation of various classes of indole derivatives, mostly those substituted in the pyrrole ring. Natural indole derivatives are discussed, including heteroauxine, gramine and tryptophan, and there is a valuable discussion of the metabolism of tryptophan. It would have been useful to have had also a section giving a general account of the properties and reactions of indole and its simple derivatives, although doubtless most of the information which could have been introduced in such a section is scattered through the chapter in its present form.

Reference is made in the prefaces to delays at the proof stage and to the fact that it has not been possible to bring the subject-matter completely up to date. Although unfortunate, this is doubtless unavoidable, especially in fields such as those covered by the present volumes, where new developments are constantly taking place. The section on the stereochemistry of the tropane group, for example, would have been presented rather differently if it had been possible to include the recent work of Prof. G. Fodor.

The books are well printed and produced and scarcely any misprints have been noticed. The numbering of the acridine ring has given some difficulty, and it is interesting to note that the editor has not felt bound to adopt current American practice. Both he and his collaborators are to be congratulated on a most valuable contribution to the literature of organic chemistry.

J. W. COOK

A FRESH APPROACH TO INTERMEDIATE BOTANY

Intermediate Botany

By L. J. F. Brimble. Fourth edition entirely revised and rewritten in collaboration with Dr. S. Williams, and with the assistance of Dr. G. Bond. Pp. x+505. (London: Macmillan and Co., Ltd., 1953.) 20s. net.

THE authors have rewritten "Intermediate Botany" by L. J. F. Brimble and brought it up to date. They have set out to provide a book suitable for candidates for the General Certificate of Education (Advanced Level) and for candidates for first-year university examinations such as those for intermediate science, arts, pharmacy, agriculture, horticulture and medicine. They were obviously faced with various fundamental decisions, and they can scarcely be expected to have produced a volume that is beyond criticism by teachers in at least some of the wide fields for which they have attempted to cater. For example, there will always be two schools of thought as to whether one should begin the session with *Pleurococcus* or with a whole plant of groundsel. The authors have in some ways chosen the best of both worlds, because they have devoted the first thirty pages or so to an interesting introduction in which they review the subject of botany and the plant kingdom as a whole. Then, when they start the real work they throw in their lot with the groundsel school, except that they use rosebay willowherb for variety.

In the next three hundred pages (approximately) the Angiosperm is treated very fully. The physiology and anatomy are both well presented in the text though the diagrams vary in quality. For example, on p. 253 the stamens of the buttercup are not shown to be extrorse; part of the diagram of meiosis on

p. 266 is not a happy choice. Elementary students find this subject difficult, and really clear drawings of a good size are essential to the elucidation of the facts. This Angiosperm section as a whole is, however, very well done and the material will be of great value to students.

The emphasis in any course must depend largely on the teacher; but one might be justified in feeling that the lower plants have been sacrificed to some extent in this volume. They occupy a total of approximately one hundred pages out of five hundred, which appears to be less weight than most teachers would expect to give them in well-balanced courses.

The book concludes with a chapter on ecology and a section on the families of flowering plants. In the latter, the need to cater for a wide range of students has tended to force the inclusion of a large number of families, where one would have preferred, for some courses, a more detailed treatment of fewer families.

On the whole, however, the book will be very valuable for the upper forms of grammar schools and for first-year students in universities. It brings out the breadth of the subject and its inter-relationship with human beings and world economy. All the way through the authors have refrained from "putting words like monochlamydeous in a series of adnate parallelograms" and have written the text in an attractive manner that will lead the student to read more widely by stimulating interest in different aspects of the subject. Suggestions for practical work occur at frequent intervals, and the material as a whole is presented with a freshness that will stimulate both teacher and student. The book is well produced with clear print and a comprehensive index.

LILY NEWTON

COMETS AND METEORS

Comets and Meteor Streams

By Dr. J. G. Porter. (International Astrophysics Series, Vol. 2.) Pp. xi+123+6 plates. (London: Chapman and Hall, Ltd., 1952.) 28s. net.

IN 1947 when the Physical Society conference was held in Manchester to discuss the new radar methods of investigating meteors, Dr. J. G. Porter gave a lecture on the subject. The present book is an expansion of this lecture and provides the most up-to-date information on the subject of comets and meteors (very little is said about meteorites, but many now think that these have originated in some way entirely different from that in which comets and meteors had their origin). The first chapter gives a general survey of the subject and deals with such matters as the increase in cometary discoveries, the mass, size, spectra, luminosity, etc., of comets, and the influence of light pressure, ending with a short reference to Whipple's hypothesis, suggested in 1950, on the origin of comets. Chapter 2, on the orbit of a comet, is almost entirely mathematical and will prove very helpful to amateur astronomers who are engaged in calculating ephemerides by the use of standard formulæ but may not always know how these formulæ are derived. A short reference is made to the computation of orbits of comets from three observations, but the author very wisely does not attempt to deal with the methods generally used for computing cometary orbits—a problem which he describes as "one of singular complexity" and which lies outside the scope of the book. Chapter 3, which is illustrated by a number of diagrams, is on cometary statistics and deals with such matters as distribution of perihelion distances, the three types of comets (parabolic, hyperbolic and elliptical), families of comets, distribution of eccentricities and aphelia, the number of comets and their origin. A brief survey is made of the theories of the origin of comets, but Dr. Porter offers no opinion on their relative merits, though after describing Oort's explanation he suggests that in the future greater importance may be attached to the study of "new" comets, "and of the perturbations by planets and stars which these comets have suffered in the past".

Chapter 4, on perturbations, will be read with great interest by members of the British Astronomical Association who belong to the Computing Section, of which Dr. Porter is the director. This Section does very valuable work in various ways—not least in computing cometary perturbations and compiling ephemerides for a number of periodic comets. This chapter shows the principles underlying the method, and a useful example of the application of mechanical quadrature is given for a body falling freely in the earth's gravitational field. Table 13 shows how the Cowell scheme is used in the case of the Pons–Winnecke's Comet during the years 1948–49 of its revolution, and other useful information on perturbed orbits is provided in this chapter.

The last three chapters deal with meteors, Chapter 5, on meteor streams, giving a general survey on such matters as visual observations, the number of meteors, modern methods of observation (including photography and radar), perturbations of meteor streams and the effect on the elements of their orbits. In the next chapter is shown how the orbit of a meteor stream is computed when the position of the radiant is known and also how corrections are made in this position when the earth's attraction and the aberrational effects due to the diurnal rotation are taken into account. While the latter is very small and can often be ignored, the former can be considerable, especially when the speeds of the meteors relative to the earth are small and the radiant is close to the horizon. The reverse problem—the determination of the radiant of a stream associated with a comet—is also dealt with, and Table 19 gives a list of cometary meteor radiants, a maximum distance of 0·1 astronomical unit between the earth's orbit and the comet being admitted.

At the end of Chapter 7, which is the last one and deals with meteor velocities, after examining all the available evidence, including photography and radar, on the velocities of meteors, Dr. Porter says he is convinced that all meteors, like comets, are members of the solar system with the exception of a relatively small number of both meteors and comets which are forced into slightly hyperbolic orbits by planetary perturbations. While there are still some who think that a fairly large proportion of the sporadic meteors have decidedly hyperbolic velocities—far exceeding parabolic velocity—the general opinion now is that errors of observation or in timing the flight or other causes are responsible for this view and that meteors must, on the whole, be accepted as members of the solar system.

This book will be extremely helpful to amateur astronomers; and even professional astronomers, many of whom have never found time for an intensive study of meteoric problems, will read it with great interest and advantage.

M. DAVIDSON

Inorganic Chemistry

An Advanced Textbook. By Prof. Therald Moeller. Pp. ix+966. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 80*s*. net.

THE term "advanced" of the sub-title of this book is of special note. The author writes for graduate and undergraduate students, and he assumes that the customary descriptive matter of the advanced text-book is known—so he omits most of it. This permits him to concentrate on the significant chemistry of the substance in question and on its general relationships. Furthermore, he maintains that those sections of physical chemistry which determine properties and behaviour are an essential part of inorganic chemistry. The discussion of these fundamental physical factors forms his Part 1 (pp. 369). The contents of this part include: atomic and molecular structure, radioactivity, the Periodic System, valency, the chemical bond, oxidation potentials, acid-base concepts, complex ions and co-ordination compounds, and non-aqueous solvents. The treatment of these principles is done more thoroughly than in many a text-book of advanced physical chemistry; and the co-ordination of the relevant factors to the interpretation of chemical action is a praiseworthy piece of work. The descriptive matter forming Part 2 is divided into eleven chapters on the basis of the Periodic System. The chemistry of the elements and of their chief compounds is considered in the light of the conclusions established in Part 1; the emphasis, therefore, is on unifying factors and interrelationships and not on the details of preparations and properties. There are an appendix on naturally occurring isotopes and one on the disintegration series. The book is well documented. The carefully planned and skilful fusion of facts and theories into an ordered system herein given should do much to promote the study of inorganic chemistry.

Methods of Logic

By Prof. Willard van Orman Quine. Pp. xxi+264. (London: Routledge and Kegan Paul, Ltd., 1952.) 16*s*. net.

IT is characteristic of the present 'climate' in which advanced mathematics is developing in the United States to find comprehensive texts dealing with logic, foundations, the theory of sets, and so forth appearing fairly rapidly. This readable book is an excellent example, and one which may well exert a wide influence. The subject-matter is covered in four main parts—truth functions, uniform quantification, general theory of quantification and, finally, glimpses beyond. There is also a select bibliography.

As one might expect, some of the most illuminating remarks occur in connexion with the discussion of identity, and in an exceptionally lucid introduction to the algebra of classes and relations. An example of the former (p. 208) is:

Cicero = Cicero, Cicero = Catiline, Cicero = Tully.

Of these, evidently the first is trivial, and the second is false, but the third is in fact true, in the sense that two different assemblages of letters denote one and the same man. Perhaps the most interesting contrast here is between this kind of identity and the traditional reluctance of the grammarian to allow that there is such a thing as a true synonym. John Ruskin, for example, would never admit that a perfect synonym existed. It is to the credit of the modern logician that his symbolism has helped so much to clear the air, as well as directing attention to the distinction between the sign and the thing signified, be it a specific entity or a universal.

F. I. G. Rawlins

Electromagnetic Fields

Theory and Applications. By Prof. Ernst Weber. Vol. 1: Mapping of Fields. Pp. xvi+590. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 80*s*. net.

IN this text-book Prof. E. Weber gives a very complete presentation of the various methods—analytical, numerical, and graphical—which are available for the mapping of static electric and magnetic fields. Analytical methods are given the most detailed attention, and there are separate chapters dealing with fields of simple geometry, two-dimensional analytical solutions, and three-dimensional analytical solutions. Numerical and graphical field-plotting methods, such as the relaxation method and the method of curvilinear squares, are treated in a single chapter, and there is in addition a chapter giving a brief outline of experimental methods of field-plotting.

The introductory sections of the book, in which the fundamental relationships for electrostatic and for magnetostatic fields are developed, have been prepared with particular attention to clarity and accuracy of exposition. Much of the material of the earlier chapters is appropriate to undergraduate courses in physics and electrical engineering; but, taken as a whole, the book constitutes an authoritative work of reference for the advanced student or research worker.

The book utilizes the rationalized M.K.S. system of units, and one of the four appendixes gives a table of conversion factors to other unit systems. References are given to a large number of the most important original sources upon which the author has drawn.

Between the Tides

By Philip Street. Pp. 175+32 plates. (London: University of London Press, Ltd., 1952.) 15*s*. net.

"THIS book", states the preface, "is intended primarily for the young naturalist", and there is no doubt that those interesting themselves in sea-shore life for the first time will find it both helpful and stimulating. The information given is, on the whole, accurate and well selected, a little being derived from recent scientific publications. The text is written in a plain and elementary style well suited to its purpose; it is free from facetious anecdotes and that attitude of wide-eyed wonder which has disfigured so many natural-history books intended for the young. The work is enlivened with lengthy quotations from Gosse, Couch and other writers of the past century, from which the young reader will be made aware that there is a historical background to seashore studies. There are a number of factual errors and some misleading statements; but these are not unduly numerous and are mostly of minor significance. In the text there are some forty line-drawings which the beginner will find useful in spite of their crudity. The book is lavishly illustrated with many photographs reproduced in half-tone on art paper. The photography is competent; but the subjects are all too often preserved specimens out of water. Some of the photographs are from life, and a few of these show real technical ability.

D. P. Wilson

VISITORS' TABLES AT COLONIAL FISHERIES RESEARCH STATIONS

By DR. C. F. HICKLING, C.M.G.

Fisheries Adviser to the Secretary of State for the Colonies

THE Colonial Office is establishing a number of fisheries research stations at suitable points in the British Colonial Empire. These stations are particularly concerned with the application and adaptation of existing knowledge, methods and techniques of fishery and of marine and freshwater biological research to Colonial problems, and this work involves, in addition to general studies of the ecological background, detailed studies of the life-histories of the fauna and of the factors which influence their growth, distribution and migration. The whole of the initial capital expenditure for these stations is being met from central research funds made available under the Colonial Development and Welfare Acts. The same source usually provides for one-half of the recurrent costs for an initial period of five years, the remaining half being divided between the territories in the region served by the research station.

The work of these stations is reviewed by the Colonial Fisheries Advisory Committee, which advises the Secretary of State for the Colonies. Apart from Colonial Office members, this Committee consists of the following: Mr. J. Croft Baker, chairman, British Trawlers' Federation, Ltd.; Dr. G. E. R. Deacon, director, National Institute of Oceanography; Mr. T. S. Leach, chief inspector of fisheries, Ministry of Agriculture and Fisheries; Dr. C. F. A. Pantin, Department of Zoology, University of Cambridge; Dr. G. Reay, superintendent, Torry Research Station (Department of Scientific and Industrial Research); Mr. F. S. Russell, director, Plymouth Laboratory; Dr. Ethelwyn Trewavas, British Museum (Natural History); Mr. R. S. Wimpenny, Fisheries Laboratory, Lowestoft (Ministry of Agriculture and Fisheries); and Prof. C. M. Yonge, Department of Zoology, University of Glasgow. Brief reports on the work of the stations are included in the annual series of reports entitled "Colonial Research" (for example, for 1951–52: Cmd. 8665; H.M.S.O.; 6*s*. 6*d*.).

Each station is locally administered by the Government in whose territory the station is situated, except that, in East Africa, administration is in the hands of the East Africa High Commission. Local committees, on which the interested and contributing territories are represented, discuss research policy with the directors. These research stations have accommodation for visiting scientists; and for hydrologists and biologists who may be interested in taking advantage of these facilities, the following brief account of the research stations is offered.

The earliest research station to be established is at Jinja, on Lake Victoria. Mr. R. S. A. Beauchamp is director, and there is a staff of four research officers. A study is being made of the distribution and life-histories of the fishes of Lake Victoria and of the other East African lakes, with special reference to species of *Tilapia*. Speciation problems in the *Haplochromis* group of Cichlid fishes are being investigated. A study has been made of the Chironomid and Chaoborid 'lake flies', and the life-history of these insects has been related to that of the elephant snouted fish (*Mormyrus*), which feeds principally on their larvæ. Recently, the spawning grounds of *Mormyrus* have been located with the aid of the echo-sounder; these fish spawn in deep water over rocks emerging from the mud. Ripe fish have been caught, and the eggs artificially fertilized.

The hydrology and chemistry of lake waters, with special reference to the production of plankton, form an important part of the research programme.

Work on aquatic molluscs is increasing our knowledge of the snail-borne helminth diseases of man, domestic animals and fish. A number of new snail vectors of *Schistosoma* have been recorded, and infection experiments carried out on them. As part of these investigations, a very complete type-collection of East African freshwater aquatic snails has been made, and is housed at Jinja.

The Station has two motor launches and a mobile laboratory for field-work.

Air passages and accommodation can be provided for visiting scientists who wish to work at this laboratory. Very valuable work has already been done by such visitors, which benefits and supplements that of the research station staff. Visitors include Dr. Margaret Brown, Dr. H. B. Cott, Mr. R. Ross, Mr. J. T. Saunders, Dr. G. S. Carter, Mr. D. E. Moorhouse and Dr. W. Holmes.

At Zanzibar there is a newly established Marine Fisheries Research Station. The laboratory was officially opened by H.H. the Sultan of Zanzibar in April 1953. The director is Dr. J. F. G. Wheeler, and two of the four scientific officers on the establishment are at work. Research, so far, has been mainly on the big surface fishes, such as the Carangids, Scombrids and Tunas, which are caught by multiple trolling, using a wide variety of experimental lures. At a later stage, when the full scientific staff is at work, hydrography, plankton and the biochemistry of mangrove muds and fish products will be included in the programme. The station has the use of a number of brackish-water fish-ponds, in which the chemical and biological changes undergone by sea-water when impounded over mud can be studied.

Full research facilities are provided. The Station has a 70-ft. diesel research drifter, and a 'landrover' for local transport. Zanzibar is situated in an area of coral reefs and mangrove swamps, and very deep water comes to within a few miles of the island.

The British West African territories are served by the West African Fisheries Research Institute at Kissy Dockyard, near Freetown in Sierra Leone. The Institute is placed on low cliffs overlooking the Freetown estuary, and backed by the Sierra Leone hills. This is one of the few points in West Africa where the coastal lands are high and where the foreshore is rocky. Seaward of Freetown there is a 60-mile wide continental shelf, which descends steeply from a depth of about 70 fathoms.

The director of the Institute is Mr. Angus Taylor, and the full establishment of scientific officers is six, of whom four are now at work. The station has three research vessels, namely, a 110-ft. steel motor trawler, and two 31-ft. motor launches. The station buildings are adapted from the headquarters, stores, workshops and living quarters of the former naval base. A freshwater research substation is now being established at Birnin Kebbi in Northern Nigeria.

Research is being done on the hydrology and biology of the Freetown estuary, with special reference to the fisheries, and a routine trawling survey from the motor launches is in progress. There is a very varied fauna of fish and invertebrates on bottoms of sand, shells, gravel and fine mud. Studies of bottom soils include estuarine muds and mangrove swamps, and a start has been made on the physical, chemical and biological changes which follow the empoldering and draining of such swamps.

With the large research vessel, a trawling and hydrographical survey of the seas lying off the British West African territories has begun, but has been interrupted by mechanical defects in the research trawler. Trawling was carried out to depths greater than 100 fathoms, where little or no fishing has hitherto been done. When the research trawler returns to service, these long-range surveys will be done throughout the year.

A little work has been done on the freshwaters of Sierra Leone; these are of an acid character and the territory as a whole is deficient in lime.

The Northern Rhodesia–Nyasaland Joint Fisheries Research Scheme has to cover waters separated as widely as Lake Tanganyika in the north, Lake Nyasa in the east, the Zambesi and Kafue Rivers in the south, and Lakes Bangweolo and Mweru, with their swamps, and the Luapula River, in the south and west. Consequently, though its headquarters will be on Lake Bangweolo, at Samfya, where a laboratory and houses are being built on a bluff overlooking the lake, the research unit must be mobile. This autumn it is starting a two-year survey of Lake Nyasa. Buildings are being prepared, and a research launch acquired. The scientific officer in charge is Mr. P. B. N. Jackson, and there is an establishment of three research officers.

At an earlier stage of development are the Marine Research Stations at Singapore and Hong Kong. Dr. F. D. Ommanney is director of the Singapore station, and Mr. J. A. Tubb is director of the Hong Kong station. The building of a laboratory and houses at Singapore has been delayed; a research vessel is being sought. Two of the establishment of three research officers are in training; one has recently undertaken a short mission to Barbados to study the fishing for flying-fish. The Research Station at Hong Kong is in association with the Department of Zoology of the University of Hong Kong, and will be staffed by graduates of that Department. A small research vessel has been laid down. Finally, provision has been made for a station for fundamental research into fish farming. A suitable site has yet to be found.

The Research Stations at Jinja (freshwater) and Zanzibar and Freetown (marine and brackish water) are now in operation, and provide research facilities for visiting workers, who will be welcomed. In certain cases, a part of the expenses (except salary) of a visiting scientist can be defrayed from funds available to the Research Stations. These Stations, being situated where seasonal changes are slight by comparison with temperate climates, and where there is a very wide range of ecological conditions, offer unusually good research opportunities. Applications and requests for information should be addressed, either to the Directors, or to the Fisheries Adviser, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

INTERNATIONAL CONFERENCE ON THEORETICAL PHYSICS

MEETING IN JAPAN

I BELIEVE that the proposal to hold a conference in Japan under the auspices of the International Union of Physics was first made at the General Assembly of the Union in Copenhagen during 1951; certainly the proposal had the strong support of the late president of the Union, Prof. H. A. Kramers. Suggestions were originally made for a conference of rather limited scope, on statistical mechanics or on field theory; but it seemed to everyone concerned that this, the first important conference on physics ever to be held in Japan and the first real opportunity for Japanese physicists to meet those of other countries, should cover a much wider field. It was decided in the end to arrange a conference to include most branches of theoretical physics on which work is being done in Japan, including field theories, meson theories, molecular structure and the physics of the solid state, and also to hold the annual executive committee meeting of the Union in Tokyo on the same occasion.

The conference was organized by the Science Council of Japan, with the collaboration of Kyoto University where the main sessions were held, and by the Physical Society of Japan. About sixty physicists from outside Japan attended, including thirty from the United States, six each from France and Great Britain, and others from Australia, Belgium, Denmark, Germany, India, Italy, Korea, Mexico, Netherlands, Sweden and Switzerland. About ten times as many Japanese physicists took part. Much of the heavy cost of bringing the foreign scientists to Japan was defrayed by special grants from Unesco and from the Rockefeller Foundation, while arrangements were made by the United States Government Agencies for bringing most of the scientific workers from that country. Within Japan, the cost of living and of travelling from place to place was borne by the organizers of the conference, money being contributed by the Japanese Government, by industry and commercial organizations, by newspapers and by many private individuals.

The main conference opened in Tokyo with a formal session, the delegates then travelling to Kyoto for the scientific meetings. These were held in three sections in parallel, the first on nuclear physics and field theory, and the other two covering various aspects of molecular physics, statistical mechanics and the physics of the solid and liquid states. In addition, more limited symposia were held in Kyoto and other centres, and in hotels in holiday resorts, on nuclear resonance phenomena, polymers, dislocations, latent image theory and on liquid helium, to mention only some of them.

The discussions on field theory and nuclear physics were attended by the largest numbers, both of Japanese physicists and of the visitors from other countries. (I am indebted to Prof. R. E. Peierls for a description of the work in this section.) For the visitors the most important result of the conference was that they learned to understand the ideas behind some outstanding Japanese papers that they had seen in print but had not adequately compared with their own methods. Probably the experience was mutual. It is, of course, a difficult time for field theory, since we are in doubt about the basic equations and are also without sufficiently powerful methods of solving them to be sure of their consequences. There was naturally much discussion on methods of approximation, including the idea that, for an approximate meson theory of nuclear forces, one should treat the interaction at large and at small distances differently. At small distances a phenomenological treatment might suffice, whereas at large distances conventional perturbation theory might be reasonably good. Such an approach was first proposed in Japan by Taketani and his collaborators, and later developed independently and more extensively by Lévy at Princeton. Other novel approximations which were discussed included an application by Tomonaga and others of his 'intermediate coupling' method to scattering problems, a new use of variational methods by Sawada, and an attempt by Brueckner, in describing the nucleon–meson interaction, to allow for the distortion of the meson wave by the presence of the nucleons. Some time was devoted to up-to-date reports on the experimental situation both in nucleon–nucleon interactions and on new elementary particles. It is evident that there is a wide range of facts to be described by a complete theory, but as yet no real clue as to how to construct one. New attempts to modify the theory included Yukawa's 'non-local' theory which contains for each field 'internal' as well as the ordinary space–time co-ordinates, and this gives one freedom to describe many types of particles in the same field. However, the theory is still too general to give specific results, and it also contains troublesome infinite degeneracies.

Another interesting modification proposed by Pais also uses additional variables; but these relate not to a second four-dimensional space-time but to the surface of a sphere, the rotations of the sphere being connected with isotopic spin. In this way one finds these rotations and the isotopic spin combining like ordinary angular momentum and spin, and this suggests a classification of some of the recently discovered particles. One may then interpret the absence or weakness of some processes not otherwise forbidden by a parity selection rule in this new space.

There was some discussion of theories with 'non-local interactions' in which one tries to avoid singularities by replacing the usual point interaction by actions over small but finite distances. Reports by Møller, Peierls and C. Bloch led to the conclusion that none of the existing forms of such a theory is capable of removing the singularities.

The last two sessions went briefly into problems of nuclear structure and nuclear reactions, and here one is on much firmer ground, since, in spite of uncertainty about the basic laws, a great many features of nuclear theory are qualitatively well understood.

In the session on the solid state, I was impressed with the quality and extent of the Japanese work on slip lines and their examination with the electron microscope. This is fitting, since the quantitative study of slip lines started in Japan with Yamagouchi. At the conference and at the additional symposia, first-class work was described by Fujiwara in Hiroshima, by Takamura in Kyoto and by T. Suzuki and Fujita in Sendai. One of the most interesting discoveries during the past few years in this field is the fact that marked work-hardening of metal crystals occurs only when they slip on more than one set of planes. In Great Britain we became aware of this owing to experimental work carried out here and in Germany since 1949; but we now find that the main facts were established by Fujiwara in Hiroshima during the War and published in the Japanese language. There is also much interesting work in Japan on the theory of dislocations. Here I think that one can still claim that the first steps were taken in Europe and America; but the Japanese physicists, in spite of an almost complete absence of personal contact with other countries, have acquired a detailed knowledge and appreciation of the published literature and are now making important contributions of their own. I was particularly interested in H. Suzuki's modification of the model of the Frank–Read source, which shows how the plane of slip could shift by one lattice plane for each dislocation produced, especially in view of the convincing experimental evidence from several centres in Japan that this actually occurs. A slip line within a crystal may thus have a thickness equal to the slip distance.

In an article of this length it is impossible to describe more than a few of the subjects discussed. The study of *F*-centres arouses great interest in Japan; and I vividly remember an informal session in which Prof. Seitz expounded for hour after hour all that he knew on this subject to a large and eager group that simply could not have enough. In fact, this was the impression that we all had—of large numbers of young workers, of great eagerness and talent. There is no doubt that fundamental research greatly attracts the youth of Japan, and that, in spite of very inadequate financial rewards, research is what they want to do.

Two other aspects of the conference deserve mention. One is the great amount of space devoted to it by the Japanese press and the popular interest that it excited. Every day the newspapers carried long articles about the proceedings of the conference, photographs of the delegates and accounts of their views on many subjects, scientific and otherwise. Reporters accompanied us to garden parties, to receptions and on excursions to the temples and gardens of Japan, and often became our very good friends, telling us what we wanted to know of the life of the country and showing us things that we might not otherwise have seen. To the question that we were always asked, what are the most important results of the conference, we could only answer that through it the Japanese physicists and those of the rest of the world have got to know each other, to appreciate each other's work, and to establish mutually stimulating contacts. This was certainly true, and made the conference well worth while.

The other point is the warmth and the charm of the hospitality that was showered upon us. Everything that could be done was done to make our stay enjoyable and comfortable, to show us the best of the old Japan and of the new Japan. At each city the leading citizens came forward to welcome us, flowers and gifts were pressed upon us, cars and interpreters put at our disposal. I expect that both sides learned much from the customs of the other. I remember how, at a farewell dinner, after which the Western delegates had spoken at some length, Prof. Tomonaga referred to the good and the bad that Japan had taken from the West, including that bad Western custom, the after-dinner speech. The Japanese custom is to give a few words of welcome before the guests sit down to dinner and no afterwards. On the occasions during our stay when this was done, with the elegant dishes of the country spread out before us, there was certainly no temptation to speak too long. Perhaps this is one of the customs that we might learn from Japan.

N. F. MOTT

TWELFTH INTERNATIONAL CONGRESS OF LIMNOLOGY

THIS Congress, like the preceding ones (see *Nature*, 162, 623; 1948) held under the auspices of the International Association of Limnology (President: Dr. Gunnar Alm (Sweden)), opened at Cambridge on August 20 and terminated at Windermere on August 30. The first to be held in Great Britain, it attracted nearly three hundred people belonging to about thirty-five different countries. On the first evening those taking part gathered at a reception at Trinity College, while on the last afternoon at Cambridge the Master and Fellows of Christ's College entertained them at a garden party. On the evening of August 21, Prof. D'Ancona (Padua) delivered the first Baldi Memorial Lecture, founded by his countrymen in memory of the late Prof. E. Baldi. Prof. D'Ancona, who spoke in English, took as his theme the stability of lake plankton communities, a topic to which Baldi and his co-workers made manifold contributions. On the evening of August 25, Dr. E. Windle Taylor (Great Britain) gave an account of the reservoirs of the Metropolitan Water Board; on August 22, Dr. J. W. Jones (Great Britain) showed a cinematograph film of salmon spawning, while other films relating to fisheries were shown on the evening of August 24.

Upwards of a hundred papers were read during the scientific sessions at Cambridge, but only some of them can be referred to here. Many discussed from one point of view or another topics that are momentarily in the forefront of limnological investigation. Papers dealing with temperature-relationships and circulation in lakes attracted much attention. While C. H. Mortimer described the effects of the earth's rotation on the internal wave pattern, B. Dussart (France) dealt with the influence of inflowing water and sublacustrine springs on thermal stratification and discussed heat-absorption and nocturnal radiation from the surface, a subject considered by H. Charnock from the meteorological point of view. A paper by H. Neumann (Israel) dealt with the second minimum of evaporation which occurs during the period of greatest heating in lakes of middle latitudes. E. S. Deevey (United States) and E. Gessner (Germany) reported on temperature-relationships in tropical South American lakes, and K. Vaas on those of shallow ponds in Indonesia. Various German speakers contributed papers on the classification of lake-types, while E. Teiling (Sweden) reported on phytoplankton indicators in this connexion.

Lake sediments were considered from many different angles. G. E. Hutchinson (United States) gave a highly stimulating account of investigations of the carotenoid pigments and amino-acids present in them, while E. S. Deevey emphasized the importance of palæolimnology as a tool in studying the geographical distribution of the organisms recognizable in the sediments. Sediments also entered largely into discussions on productivity. F. R. Hayes (Canada) described experiments demonstrating the role of bacteria at the mud–water interface on the uptake of radiophosphorus and suggested that artificial increase of the area of the bottom might have the same effect as addition of nutriments (fertilization). D. S. Rawson (Canada) laid emphasis on the shape of the basin as a factor influencing productivity in large lakes. E. A. Thomas (Switzerland) reported the results of monthly estimations and analyses of sedimented material, while H. Järnefelt described similar observations made in southern Finland. H. Dammas (Belgium), described the important contribution made by the phytoplankton to sediments in shallow lakes of the Congo, while J. Symoens (Belgium) gave an account of tufa deposits due to Chironomid larvæ, associated with *Phormidium incrustatum*. The bottom fauna was dealt with by K. Berg (Denmark) and F. Lenz (Germany), while J. H. Mundie (Great Britain) discussed the distribution of Chironomid midges in a Thames reservoir.

As regards other aspects of productivity, W. Ohle, in considering the rapid eutrophy of many North German waters, pointed out that even purified sewage effluents contribute materially towards mineral enrichment of surface waters, while a paper by G. A. Prowse (Sudan) discussed the contribution of the flora as a whole to the productivity of a water. W. Rodhe (Sweden) reported on the probable role of minute and partly heterotrophic green algæ in subarctic lakes in maintaining during winter a zooplankton of about the same magnitude as is found in summer, and G. E. Fogg discussed the importance of polypeptides excreted by algæ in relation to productivity.

Among papers dealing directly with plankton, mention may be made of those of J. Rzóska (Sudan) on that of the White Nile, which attains a maximum during the accumulation of water above the dam south of Khartum; of V. Tonolli (Italy), who considered the fate of zooplankton washed into rivers from the surface waters of lakes; of W. Schmitz (Germany), on the occurrence of water-flowers in flowing waters; of J. F. Talling, on the light-relations of the phytoplankton; and of M. Shilo (Israel), on the use of ammonium sulphate in the control of the toxin-producing phytoflagellate *Prymnesium*. O. Ravera (Italy) and U. Reen (Denmark) discussed seasonal variation in reproductive rate of pelagic Copepods. R. Margalef (Spain) discussed the influence of higher temperatures on morphology of freshwater organisms. A. A. Aleem (Egypt) described the use of triphenyltetrazolium chloride in the measurement of plankton populations, while A. van der Werff (Netherlands) reported on a new method for cleaning diatoms using hydrogen peroxide and potassium permanganate.

Many speakers dealt with aspects of the distribution of freshwater organisms. S. Stanković (Yugoslavia) considered speciation in Lake Ohrid. H. B. Hynes (Great Britain) and S. G. Segerstråle (Finland) discussed the distribution of *Gammarus* in Britain and Scandinavia respectively, J. Illies (Germany) emphasized the importance of Plecoptera owing to their restriction to definite temperature ranges and speeds of current, while K. H. Mann dealt with the factors determining the distribution of leeches, and A. G. Dahm (Sweden) gave an account of the recent immigration into Europe of the Planarian *Dugesia tigrina*. C. Kosswig (Turkey) discussed the marine element in the fish-fauna of freshwater lakes near the Sea of Marmara. Other speakers considered aspects of the introduction of fish. P. Vivier and E. Hubault discussed the causes of the lack of success in introducing Salmonidæ into French waters, E. G. Calderon dealt with the introduction of pike into Spain, J. R. Dymond gave an account of the introduction and spread of *Salmo trutta* and *Cyprinus carpio* in Canada, and D. Hey (South Africa) described the culture, especially of bream, in the final effluent from a sewage works.

Of other papers dealing with fish, mention may be made of those of S. Runnstrom (Sweden), who described the damage to roe of char resulting from the winter-lowering of the water-level in an impounded lake; of H. D. Slack (Great Britain), dealing with factors affecting the survival of *Coregonus* eggs; and of E. D. Le Cren with those conditioning survival of perch after hatching in Windermere.

On the botanical side A. Lundh-Almestrand discussed the distribution of diatoms in Scanian lakes in relation to their geological structure, F. Hustedt (Germany) gave an account of the influence of temperature on the diatoms of solfataras in Salvador, B. Knudsen dealt with the distribution of *Tabellaria* in the Lake District, while G. Lohammer (Sweden) discussed the introduction of foreign macrophytes.

On the applied side O. Jaag (Switzerland) and D. M. Newitt dealt with general aspects of pollution, F. T. K. Pentelow and J. R. H. Allan with its effects on the distribution of fish, and R. W. Butcher with organisms indicative of stages in recovery from pollution. T. Braarud (Norway) discussed pollution in the Oslo Fjord, while C. J. Rasmussen described pollution by silage juices in Denmark. H. Jakob and M. Nisbet (France) gave an account of experiments on the toxic effects of derivatives of ammonium compounds on algæ and fish, while K. Wuhrmann (Switzerland) and D. W. M. Herbert discussed the influence of various factors on the toxicity of poisons to fish. E. Hubault (France) considered toxicity in relation to molecular structure, while A. B. Wheatland dealt with the influence of traces of oxygen in bringing about absence of sulphides in polluted estuaries.

Various British workers treated of matters concerned with sewage disposal. S. Baines *et al.* described the correlation between the peritrichous ciliate population and the quality of the effluent from activated sludge, H. Painter discussed the factors affecting the growth of fungi in percolating filters, while T. G. Tomlinson considered means of controlling their growth. E. Weise described the use of effluents in German agriculture and W. Husmann gave an account of recent methods of effluent purification in Germany.

Other speakers dealt with water supply. E. Mercier (Switzerland) described improvements in the water of a eutrophic lake resulting from artificial subsurface aeration, A. Guelm (France) discussed the role of bacteriophage in self-purification, and J. Wautier (France) described experiments demonstrating the importance of the biological film in sand filters in retaining *B. coli*. A. T. Palin discussed chlorination, while L. A. Allen, dealing with a new method of estimating numbers of fæcal bacteria in a sewage effluent, referred to their rapid decrease which is not accounted for by dilution.

At the final session in Windermere, the present officers of the International Association of Limnology having indicated their desire to retire, Prof. F. E. Fritsch was elected president and Dr. T. T. Macan general secretary. During the opening session at Cambridge, Naumann Medals were awarded to Prof. Lenz (Italy) and Dr. L. Findenegg (Austria).

Visits to Wicken Fen, the Norfolk Broads, the Luton sewage disposal works, and the Water Pollution Research Laboratory at Garston were arranged during the days spent at Cambridge. The journey to Windermere was made by coach, and occupied three days, with visits to the valleys of the Wharfe and Ure, Wensleydale, Ladybower Reservoir (Bamford), and the sewage works of Birmingham at Barston and Minnworth and of Bradford. During the two days spent at Windermere, one was devoted to inspection of the laboratory of the Freshwater Biological Association and of the experimental hatchery and fishponds at Wraymires, the other to tours in the Lake District. A small number of members visited the Rivers Avon and Test in a pre-congress excursion, while about a hundred took part in a four-days excursion into Scotland after the end of the Congress, visiting the Glasgow University Field Laboratory on Loch Lomond, the Brown Trout Research Laboratory and the Tummel-Garry hydroelectric installations at Pitlochry, and returning via Inverness, Loch Ness and Fort William to Glasgow. A small party then proceeded on a seven-days excursion in Ireland.

F. E. FRITSCH

A FOSSIL HUMAN MANDIBLE FROM A LEVALLOISO-MOUSTERIAN HORIZON IN CYRENAICA

By DRS. C. B. M. McBURNEY, J. C. TREVOR and L. H. WELLS

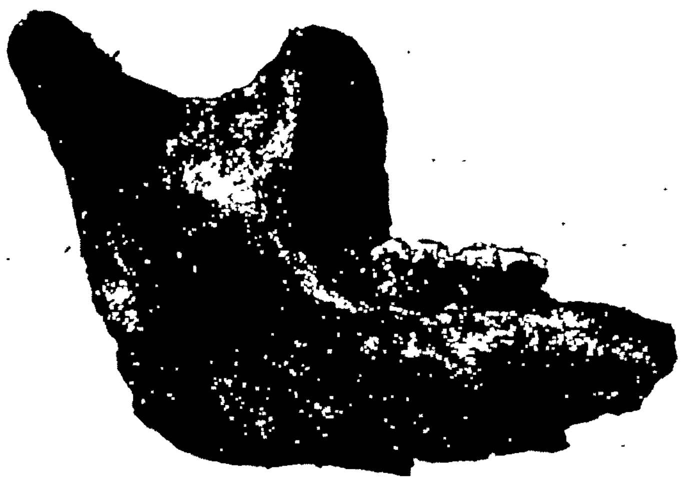
Department of Archæology and Anthropology, University of Cambridge, and Department of Anatomy, University of Edinburgh

IN 1947 and 1948, and again in 1951 and 1952, expeditions sponsored by the Department of Archæology and Anthropology at Cambridge visited northern Cyrenaica to study the Pleistocene geology and prehistoric archæology of the Gebel Akhdar coastline[1]. Since the region had been largely unexplored from this point of view, the work of the first two seasons was concentrated on establishing so far as possible the outlines of the geological and archæological sequences during the Pleistocene and their correlation. The final report on it is now in the press. The two following seasons, in 1951 and 1952, were largely devoted to the investigation of a site discovered at the end of the 1948 season—the Haua Fteah or Baker's (literally Dough-Kneader's) Hole.

The Haua Fteah Site (C. B. M. McB.)

The fossil human mandible discussed below was found at Haua Fteah in August 1952. Despite its incomplete state, the specimen is of special interest owing to the exceptionally clear evidence of geological dating and archæological associations peculiar to the site. This consists of a vertical shaft-like cavity, oval in plan and 80 yd. in minimum diameter, originally partially or wholly closed at the top by a dome-shaped roof. Apparently as a result of its situation close to the shore forming the northern margin of the limestone plateau which constitutes the Gebel Akhdar, about half this roof has been eroded away. The remaining roofed-in portion of the shaft is roughly semicircular in shape and 80 yd. in diameter; the seaward part is open to the sky. Sediments in the seaward part are probably to a large extent subaerial in origin and would appear to have been carried under the overhang as they formed, partly by the action of occasional floods and rain-wash in the spring. This would explain the remarkably regular horizontal stratification observable in a sounding-trench opened in the roofed-in area, which has now reached a depth of 28 ft.

The roofed-in area is regularly inhabited at the present day, and it seems to have been so in the past throughout the period represented by the deposits thus far exposed. Reading from top to bottom, these present the following archæological and geological indications. Recent and Roman occupational debris occurs from 0 to – 4 ft. From – 4 ft. to – 7 ft. numerous flint artefacts and sherds of rough pottery represent a Neolithic culture with some points of resemblance to Miss Caton-Thompson's Neolithic stage of the Fayum. No pottery or pressure-flaked implements are found below – 7 ft., but from – 7 ft. to – 8½ ft. a relatively high proportion of very minute microlithic tool types is met with. Below this, again, the bigger tool forms, such as large backed-blades, become progressively more common down to – 16½ ft. Beneath a sterile zone further assemblages at – 18 ft. show a typical Levalloiso–Mousterian industry which continues to be recognizable down to the lowest point reached at – 28 ft. The mandible was found among an assemblage of food-bones bordering a hearth at – 23 ft.; it was thus covered by a deposit of at least 5 ft. containing typical Levalloiso–Mousterian cultural debris. An interesting feature already noticed in other Levalloiso–Mousterian finds in this region is their remarkably close resemblance in most details to the corresponding industries in Palestine.



Medial aspect of the Haua Fteah jaw (natural size)

On the geological side, a change in the character of the deposits can be shown to coincide approximately with that of the industries. From – 8½ ft. to – 15 ft. the deposits are marked by a very high proportion of angular fragments of limestone which owe their origin to thermoclastic weathering of the walls and roof of the cave. Above – 8½ ft. these become progressively rarer, while below – 16 ft. they are virtually absent. From – 17 ft. to – 28 ft. there is a great increase in the frequency and extent of stalagmitic concretions, rare above this zone.

The climatic interpretation suggested by Dr. R. W. Hey, who examined the section at the end of the excavation, is that the lower portion represents a phase of relatively temperate and damp conditions, followed by one of dry conditions with well-marked winter frosts that gradually gives way to the dry temperate conditions of the present time. As to the absolute dating of these two phases, it would appear that neither can be correlated with the two major climatic phases of early Würm date previously recognized in the area, namely, one of damp temperate conditions followed by a period of winter frost-action with low rainfall, since the second of these is associated with Levalloisian industrial remains. Moreover, if the last-mentioned phases can, as appears highly probable, be correlated with the two early Würm phases recognized in southern Italy by A. C. Blanc[2], there is every reason for placing the Levalloiso–Mousterian zone at Haua Fteah that contains the mandible *no earlier* than the second Wurm interstadial.

The Haua Fteah Jaw (J. C. T. and L. H. W.)

The fragment consists of the left ascending ramus and portion of the body with two teeth of the permanent dentition, M_2 and M_3, still in place. Its outer surface is crushed and uneven but the inner surface is well preserved. The crown of M_2 is much worn and the cusp-pattern therefore obscure. The wisdom tooth, however, seems to have erupted only a short time before the subject's death, since, apart from a certain amount of attrition on its proximal margin, the occlusal surface is unabraded. It bears five cusps but displays the modern cruciform rather than the archaic classical *Dryopithecus* pattern and has no discernible anterior or posterior fovea. The largest cusp is the anterior buccal (protoconid), and the European Neandertal 3–2 contact, noted by Gregory in all the permanent lower molars of the Le Moustier youth and in the two of the Ehringsdorf child that have erupted[3], does not exist. Instead, the general form of M_3 is similar to the corresponding tooth of the 'Neandertaloid' woman, Tabun I, from Mount Carmel in Palestine[4]. Skiagrams indicate the absence of true taurodontism as described by Tratman[5]. The dimensions of the teeth, although somewhat small, do not provide an adequate basis for sexual assessment. On the other hand, a crude analysis of the metrical features of the ramus by the method of assigning 'marks', used by Pearson and Bell and by Morant[6], suggests that the sex of the person to whom the mandible belonged was probably female. Slight as it is, the evidence at our disposal tends to identify the owner of the jaw as a young woman, aged perhaps between eighteen and twenty-five.

Morphologically, the Haua Fteah fragment is distinguished by the square appearance of the ascending ramus, which is emphasized by the shallow sigmoid notch and low blunt coronoid process. This appearance of the ramus seems to be due chiefly to a building-out of its anterior border, that is, the portion to which the temporal muscle is attached. It is further accentuated by the relative lowness of the body of the mandible where it joins the ramus; the height of the ramus above the alveolar plane is, by contrast, great. Despite the shallow sigmoid notch, the articular surface of the condyle is boldly convex.

In the best-known specimens of European Neandertal mandibles (La Chapelle-aux-Saints, La Ferrassie, La Quina, Krapina) the ascending ramus is conspicuously narrower than in the Haua Fteah fragment; but that of the presumably female Malarnaud jaw would assume a very similar appearance if its anterior border were built out to the same degree. All these European Neandertal mandibles display a broadly truncated angle; although the posterior border in the Haua Fteah fragment is corroded, it does not clearly indicate such a truncated outline. In this respect the specimen more closely resembles the Mount Carmel mandibles. Among these the Tabun mandibles, and especially the female Tabun I, are nearest to the Haua Fteah fossil, a fuller account of which will be published by us in the *Journal of the Royal Anthropological Institute*, Vol. 83, Part I.

OBITUARIES

Prof. M. Lugeon, For.Mem.R.S.

At Lausanne on October 23, Maurice Lugeon passed away, having reached the ripe old age of eighty-three. In him we lose one who may fairly be regarded as the chief participant in the most exciting achievement that stands to the credit of geological science.

Spectacular results regarding Alpine structure had indeed been obtained before Lugeon's day, but in 1893 something of a different order was introduced through Schardt's announcement of the far-travelled nature of the Prealps that extend from Lake Geneva to Lake Thun. Lugeon was closely connected with Schardt's discovery, and afterwards did more than anyone else to develop the ideas thus liberated, and to provide a comprehensive interpretation of the Alps as a whole. In 1885, Lugeon, only fifteen years old, began to accompany a junior assistant engaged upon the official geological survey, 1 : 80,000, of the French portion of the Prealps. By 1891 he had advanced to the position of rucksack-carrier to Renevier, the principal surveyor in his district. This resulted in an introduction to the director, Michel-Lévy, who, impressed by the part played by the 'petit homme' in a field conference, tried his mettle as an independent mapper. The result was satisfactory, and Lugeon was retained for some years to work for the French survey. In 1893, along with Renevier, he led an excursion of the Swiss Geological Society to the Chablais district upon which he was engaged. Here he demonstrated, on new fossil evidence, the existence of an important area which has peripheral Trias and Jurassic resting almost everywhere upon Tertiary strata. For him, in his youth and inexperience, the structure seemed to be a mushroom-fold, in which older rocks were supposed to have risen centrally through younger, thereafter to spread outwards in all directions. This was a structural mistake, as Marcel Bertrand warned him in conversation; but his demonstration of age relations provided Schardt with an essential clue to the correct interpretation. By 1895 Lugeon was almost certain that Schardt was right, and we find him closing a great memoir on the "Région de la Brèche du Chablais" with the words: "It is with doubt, mingled, however, with conviction, that I finish this work". Next year he declared himself completely satisfied.

Among the multitude of his subsequent papers we may perhaps single out for special gratitude "Les grandes nappes de recouvrement des Alpes du Chablais et de la Suisse", which was circulated in proof during a triumphant excursion, 1901, and "Les Hautes-Alpes calcaires entre la Lizerne et la Kander", 1914–18. One of his last services to science dates from 1950, when he presided over a 'réunion géologique en Provence pour commémorer le cinquantenaire des œuvres de Marcel Bertrand'. It was good to find the old hero defending some of Bertrand's tectonic discoveries, all too readily abandoned by the present generation.

In the utility field, Lugeon has also won distinction as a consultant on dam sites, both at home and abroad.

Lugeon's many honours include, in addition to the Wollaston Medal of the London Geological Society, the following appointments: honorary professor of the University of Lausanne, where for many years he taught; foreign member of the Paris Academy of Sciences, and of the Royal Societies of London and Edinburgh; Grand Officier of the Legion of Honour, France.

He is survived by a widow and son.

E. B. Bailey

Mr. A. W. Ashby, C.B.E.

Arthur Wilfred Ashby, whose death occurred at Oxford on September 9 at the age of sixty-seven after a few days illness, had a world-wide reputation as a student of agricultural organization and rural social life. Born at Tysoe, in Warwickshire, he was the eldest son of Joseph Ashby, a farm-worker and smallholder, a Methodist lay-preacher, and a friend and colleague of Joseph Arch, the organizer of the first Agricultural Labourers' Union. Arthur Ashby was educated at the village school, proceeding thence after a few years work on his father's holding to Ruskin College, Oxford, as the first holder of the Charles Buxton Scholarship, recently endowed, tenable by the sons of farm-workers. In 1911, he was awarded the University diploma in economics and political science, and in the following year the Board of Agriculture awarded him a research scholarship in agricultural economics; its terms provided for two years study at Oxford in the newly-founded Institute for Research in Agricultural Economics, to be followed by a third year spent in some approved research centre overseas. In Ashby's case the First World War restricted the choice to one of the American universities, and it was to Wisconsin that he went.

Returning to Oxford in 1915, an honorary Fellow in political economy of Wisconsin, he began a study of the history of allotments and smallholdings which was published by the Institute in 1917, and although it was supplemented by later writers, it remains the classic on the subject. A period of work for the Board of Agriculture followed, during which he was occupied mainly in the Food Production Department; but he had a large share, also, in the provision of data for the early work of the first Agricultural Wages Board, set up in 1917. He returned to Oxford in 1920, remaining there until 1924, when he was elected lecturer in agricultural economics in the University College of Wales, Aberystwyth, an appointment which was raised to a professorial chair five years later. Thus he continued until 1946, when he returned once again to Oxford as director of the Agricultural Economics Research Institute, to retire finally in December last.

All through his life, Ashby showed an immense capacity for work. His early experiences as a member of a farm-worker's family at the end of the past century, and his own achievement of an education from village school to university standard in the days when this was not an easy accomplishment, had given him a deep and lasting interest in education and its provision on a wider scale for those capable of profiting by it. At Aberystwyth he created the school of agricultural economics, and when that was established as the foremost place of study of the subject in the United Kingdom, he went on to found a postgraduate school which achieved an international reputation, attracting graduate students from all parts of the world. This interest was further developed during his last years, when the research institute at Oxford became the Mecca of students from the Commonwealth, the United States and other places. Subsidiary to this work was his interest in administration. So early as 1919 he had been a member of the Royal Commission on Agriculture, and three years later he served on a departmental committee on prices of farm produce. Marketing problems became his particular study, especially co-operative organization, and when the co-operative movement in English agriculture suffered its lamentable collapse in 1920, more credit was due to him, probably, than to any one supporter that the Welsh Agricultural Organization Society survived, to extend its influence in Welsh rural life in subsequent years.

Other bodies on which Ashby served with distinction were the second Agricultural Wages Board, set up by the first Labour administration in 1924, and the councils of agriculture for England and for Wales. He did much to promote the good of the Young Farmers' Clubs movement, and the efforts of the Women's Institutes to secure better conditions in rural social life.

From this record it will be apparent that Ashby's main preoccupation was the human side of the work that offered, and that his direct contributions to economic research and its literature were subordinated to it. Nevertheless, the influence which he exercised on the development of his subject cannot be over-estimated, and he was an inspiration to all those—and they were many—with whom his life brought him into contact. C. S. ORWIN

Mr. James Fairgrieve

THE death of James Fairgrieve at the age of eighty-three removes one of the few remaining members of the band of reformers whose work has given us the modern concept of geography, and who have seen in their lifetime its firm establishment throughout the schools as a subject of major cultural value and in all British universities as a discipline of comparable worth—all largely as a result of their own activities. A son of the manse, he was born at Saltcoats in 1870 and enjoyed the advantages of a peripatetic Scottish education at Saltcoats, Ardrossan and Glasgow before proceeding as an Exhibitioner in both cases to Aberystwyth and to Jesus College, Oxford, where he graduated M.A. His early interests were classical and mathematical, and for periods in his early life he held the posts of mathematics master at Kelso and Campbeltown before appointment as head of the New Southgate High School in London. But he fell under the same spell as Herbertson, with whom he worked at Oxford, Halford Mackinder, under whom he studied at the London School of Economics, B. B. Dickinson of Rugby, and H. J. Fleure, to appreciate in the reform of geography the keystone of a new humanist teaching.

In 1907 Fairgrieve gave up his headship to become geography master and second master at the William Ellis School in North London. There he established what was perhaps the first 'geography room'—a well-equipped room set apart for the teaching of geography and which he regarded as important a necessity as a laboratory for chemistry or for physics. His view in this regard has now become fully accepted and the provision of such a room in schools is standard practice. He was forty-two when he was appointed to the post of lecturer in education with special reference to geography at the old London Day Training College for Teachers, afterwards the Institute of Education of the University of London. There he was destined to wield a remarkable influence for nearly a quarter of a century (1912–35) over successive generations of teacher-trainees taking their teacher's diploma after graduation in the University of London. In those years he seemed to change little. Tall, cadaverous, with a slight stoop, an unruly shock of iron-grey hair and an unkempt walrus moustache, he talked to his classes as if they were not there, yet with a burning enthusiasm which never failed to impress and endear. A martyr to digestive troubles, he subsisted for years on a small, thin, well-done piece of steak with nothing else; in later years he felt the cold increasingly, and seemed rarely to emerge from a great shaggy woollen overcoat which only served to enhance a vivid personality.

Fairgrieve neither under-estimated nor scorned the different ways of achieving reform. He knew that one may preach reform in the teaching of a subject for years without result: put one question in a public examination paper of a new type and teachers will adapt their courses overnight. Give the teacher the text-books with the new view and reform is assured. So he did an immense amount of examining and wrote many text-books. Most of the latter were in conjunction with Ernest Young—a short, rotund, insatiable traveller and *bon viveur*. Especially through the six books for the primary school and the three books for the secondary which formed the set of Fairgrieve and Young's "Human Geographies" (which have passed through innumerable editions), geography became something quite different in British schools. Critics to-day may say that the pendulum swung too far: in stressing the human aspects the essential physical basis and logical approach tended to be lost; but this was never intended by Fairgrieve himself. He believed firmly in personal observation for himself and the youngest school child alike, and so developed his interest in local and regional surveys and in microclimatology.

The film was hailed as a powerful new instrument in education, and it was natural to find Fairgrieve not only president of the Geographical Association

(1935), and vice-president of the Royal Meteorological Society (1932–33), but also original member of the Commission on Cultural and Educational Films. His sphere of interest widened when during 1927–35 he held the post of head of the Department of Colonial Education concurrently with his lectureship (readership from 1931) at the Institute of Education. Although he retired under the age limit in 1935, he never retired from active geographical work. As a result of an unfortunate accident he was temporarily crippled, and if he cursed mildly at the inconvenience of a wheel chair it did not deter him from attendance at the executive meetings of the Geographical Association to the very last, nor did his genius for helpful friendship ever leave him. *O si sic omnes!*

L. Dudley Stamp

NEWS and VIEWS

Royal Society: Medal Awards

The following awards of medals have been made by the president and the Council of the Royal Society: *Copley Medal* to Prof. A. J. Kluyver, For.Mem.R.S., for his distinguished contributions of a fundamental character to the science of microbiology; *Davy Medal* to Sir John Lennard-Jones, K.B.E., F.R.S., for his distinguished work on the applications of quantum mechanics to the theory of valency and to the analysis of the intimate structure of chemical compounds; *Hughes Medal* to Sir Edward Bullard, F.R.S., for his important contributions to the development, both theoretical and experimental, of the physics of the earth.

Nobel Prize for Chemistry for 1953: Prof. H. Staudinger

The chemistry of macromolecules has become so commonplace and so well defined that it is difficult to realize how hard the pioneers had to work to convince their scientific colleagues that macromolecules existed at all. The award of the Nobel Prize for Chemistry to Prof. Herman Staudinger sets a seal on this achievement. He was one of the pioneers of the subject long before it became of popular appeal. Many of the basic ideas about macromolecules were beginning to be accepted about the mid-thirties, but for many years before this date Staudinger was one of the very few who showed, by the use of the classical methods of organic chemistry, that small molecules form polymers not simply by a physical process of aggregation but by real chemical interaction. He demonstrated that linear molecules could be built up synthetically in this way by a variety of processes and, what is more, maintain their individuality even though they are subject to chemical modification. Again by classical methods he showed how it was possible to build up high-polymer net-works, and that such net-works would only expand to a finite extent if immersed in suitable solvents. One of his best known contributions is the establishment of the relationship between the viscosity of a solution of a high polymer and its molecular weight. The utilization of this relation permitted, by extrapolation, the estimation of molecular weights of high polymers in molecular-weight regions where no other method was at that time available. Although the relationship has been modified as more knowledge became available about these matters, viscosity methods are, without doubt, the most extensively used as a convenient and simple means of obtaining information about molecular weights of very many polymers. Nobel Prizes are often awarded for an outstanding discovery that ultimately has wide ramifications: with Prof. Staudinger it is the reward for a life-time of effort in a field that has only comparatively recently been accepted as a growing and important branch of both physical and biological science.

Engineering at University College, Dundee: Prof. J. Dick

Dr. J. Dick, who has been appointed to the chair of engineering and drawing in University College, Dundee (University of St. Andrews), as from April 1, 1954, graduated from the University of Glasgow with first-class honours in electrical and mechanical engineering in 1930. He worked in industry with the Albion Motor Car Co. before joining the late Prof. F. C. Lea at the University of Sheffield as a research assistant. A few years later he became a member of the mechanical engineering lecturing staff at that University, and in 1933 received the degree of Ph.D. Later he was appointed to his present post, the Donald Pollock readership in engineering science in the University of Oxford. Though his interests have been concerned mainly with mechanical engineering, they cover a wide range of subjects. He has been concerned with investigations on stresses in wire drawing, the fatigue of engineering materials, mechanical vibrations and lubrication, and has worked on boundary layers and heat transfer in fluid flow. He has published papers on most of these subjects. Prof. Dick is a member of the Institution of Mechanical Engineers, and has taken an active interest in the affairs of the Institution, having acted as honorary secretary of the Yorkshire Branch for five and a half years during the period 1940–45. In taking up the chair at Dundee, Prof. Dick is returning to his own part of the country, as he is a native of Fife.

Work on Guided Missiles at Woomera

In the House of Commons on October 27, in reply to a question regarding his recent visit to Woomera in connexion with the guided rocket programme, and his discussions with the Australian Government, the Minister of Supply, Mr. Duncan Sandys, stated that it had been agreed that the United Kingdom Government should, in future, bear the cost of any further work of this kind which might be done in Australia to its order. The Australian Government has agreed to take over a larger financial responsibility for range equipment ordered by it in the United Kingdom. Apart from basic research, which is not tied to a particular weapon and which goes on continuously, there are three main phases in the development of guided missiles. The first is the design and construction of prototypes; the second, the carrying out of trials and the introduction of modifications indicated to be necessary; and thirdly, there is the manufacturing phase, in which the aircraft or rocket goes into quantity production. It is in the trials stage, said Mr. Sandys, that the vast and well-equipped Woomera range is of such immense value. Both Governments are agreed that this important defence project should continue to be treated as a joint enterprise.

Use of Atomic Energy in Britain for Electrical Power

In a debate in the House of Commons on the fuel and power industries, held on October 26, the Minister of Fuel and Power, Mr. Geoffrey Lloyd, indicated that we are likely to get useful quantities of electricity from the new nuclear establishment at Calder Hall in Cumberland, and also from the new breeder reactor. It is expected that about 50,000 kW. would be generated as the result of these nuclear activities, and they would provide the data on which future atomic generating stations would be based. Mr. Lloyd stated that there is no reason why atomic power stations should not before long make a useful addition to power resources in Britain. In reply to a further question to the Minister of Supply on October 27, regarding scientific advances during the past two years in using nuclear energy for industrial, domestic, transport and other peaceful purposes, Mr. A. R. W. Low, Parliamentary Secretary to the Ministry of Supply, stated that design studies on a nuclear-power station, using natural uranium as a fuel, have been completed, and an experimental power station of this type is being constructed at Calder Hall. A low-power breeder reactor is nearing completion at Harwell. Design studies are being carried out on a higher-powered reactor of this type, and are also proceeding on other types of reactors which might be suitable for development of power. The application of radioactive isotopes to industrial, medical and research purposes continues to extend, and plans are being made to increase the facilities for their production.

Pest Infestation Laboratory: New Biochemistry Building

A new building for biochemical research at the Pest Infestation Laboratory, Department of Scientific and Industrial Research, Slough, Bucks, was opened by Sir Ben Lockspeiser, in the presence of Mr. G. V. B. Herford (director of the Laboratory) and members of the Pest Infestation Research Board, on November 6. Biochemistry at this Laboratory includes studies on mechanisms of insecticidal action, and on the contamination of stored food products by insecticides and fumigants. Much of the work has been characterized by the extensive use and development of radioactive tracer techniques. The building is of single-story construction and consists of ten laboratories, cloak rooms and boiler room. Two principal end laboratories provide for 'semi-hot' radiochemical and radiobiological work. Each of these contains a three-unit high-efficiency fume chamber provided with stainless steel tray working areas. Other features include two insulated temperature-controlled rooms ventilated with dust-free air for radiometric and enzyme assay respectively. Service points are mounted clear of all working bench surfaces, and have front bench panel controls. Sink wastes run directly to two external drains provided with inspection covers throughout their lengths and a delay tank for monitoring and decontamination. Mr. F. P. W. Winteringham (officer-in-charge of biochemistry in the Laboratory) was responsible for the basic layout of laboratories and services. Throughout planning and construction there was a close and successful co-operation between the scientific personnel and Ministry of Works architects concerned (Messrs. R. J. Sneller and A. F. J. Hannaford).

Anglo-Italian Mixed Commission

The Anglo-Italian Mixed Commission of ten members established under Article XII of the Cultural Convention, recently ratified by the British and Italian Parliaments, held its first series of meetings in London from October 26 onwards, under the chairmanship of Sir Ronald Adam. The other members of the British section were Prof. E. R. P. Vincent, professor of Italian in the University of Cambridge; Prof. J. Read, professor of chemistry in the University of St. Andrews; Mr. D. C. Riddy, Ministry of Education; and Mr. K. R. Johnstone, British Council. Lord Crawford and Balcarres, who is also a member of the Commission, was unable to be present. The Italian section was led by Signor Bartolomeo Migone, director-general of cultural relations in the Italian Ministry of Foreign Affairs. Cultural relations between Italy and Britain were firmly established before the signing of the Cultural Convention, the declared object of which is to give the fullest possible support to exchanges covering the intellectual, artistic, scientific, technical and educational activities of each country. At its first series of meetings in London, the Commission reviewed the terms of the Convention in detail and examined projects for future development. The next series of meetings of the full Mixed Commission will be held in Rome. The British Council is designated by the British Government as their principal agent for the execution of the measures falling within the scope of the Convention.

Reclamation of Deserts

A recent issue of *Trees* (17, No. 2; 1953) includes several articles on the important question of the spread of aridity, notably in the tropical and subtropical regions, with accounts of current work for its prevention or reduction and the reclamation of affected areas in the U.S.S.R., China and elsewhere. Under the title of "The Recovery of the Sahara", R. St. Barbe Baker refers to his personal experiences of the problems involved and the part he would like to see taken by the society he started some years ago under the name "The Men of the Trees". While some of the proposals, such as "carrying out surveys, studies and pilot schemes", and "fostering a centre for education and research in the forestry aspects of reclaiming the bad lands", are far beyond the capacity of the society, if indeed appropriate to it, any constructive action helping to direct public attention to the urgent need for realization of the dangers of the situation and to stimulate appropriate action is worthy of support. It is, however, important to avoid representing as proved, or at least commonly accepted beliefs, what are actually little more than unsubstantiated opinions or subjective impressions; several examples of infringement of this principle could be selected from the article quoted.

American Association for the Advancement of Science: Meeting in Boston

The one hundred and twentieth meeting of the American Association for the Advancement of Science will be held in Boston, Mass., during December 26–31, under the presidency of Dr. E. U. Condon, director of research, Corning Glass Works, and director during 1945–51 of the U.S. National Bureau of Standards. The Association is a non-profit organization with four aims—to further the work of scientists, to facilitate co-operation among scientists, to make science more effective in promoting human welfare, and to increase public understanding of science—and the theme this year will be "Scientific Resources for Freedom". For the most part the meeting will be divided into sessions arranged by the Sections of the Association, which are as follows: (*A*) mathematics; (*B*) physics; (*C*) chemistry; (*D*) astronomy; (*E*) geology and geography; (*F*) zoological sciences; (*G*) botanical sciences; (*H*) anthropology; (*I*) psychology; (*K*) social and economic sciences; (*L*) history and philosophy of science; (*M*) engineering; (*N*) medical sciences (with sub-sections (*Nm*) medicine, (*Nd*) dentistry and (*Np*) pharmacy); (*O*) agriculture; (*P*) industrial science; and (*Q*) education. The Association has 48,500 individual members, and with it are associated or affiliated 245 societies, the aggregate membership of which exceeds a million. There will be approximately three hundred sessions, made up principally of some 1,800 short papers; the Sections of the Association are sponsoring about forty symposia, and the participating societies are arranging ten symposia. In addition, the Association is holding two general symposia, on "Species which Feed Mankind" and "The Sea Frontier", respectively. During the special evening sessions at the meeting the following addresses will be delivered: December 27, "The Design and Mechanism of Muscle", by Prof. A. V. Hill, past president of the British Association for the Advancement of Science, and "Sicily, the Forgotten Island", by Luis Marden, staff member of the National Geographic Society; December 28, the presidential address of the retiring president of the American Association, by Dr. Detlev W. Bronk, president of the National Academy of Sciences; and December 30, "Science and Social Conservatism", by Dr. Leonard Carmichael, secretary of the Smithsonian Institution. Further information on the public meeting can be obtained from the acting administrative secretary, Dr. Raymond L. Taylor, A.A.A.S., 1515 Massachusetts Avenue, N.W., Washington, D.C.

University of Leeds

The University of Leeds has conferred the title of emeritus professor upon the following on their retirement from their respective chairs: Prof. F. Challenger (organic chemistry); Prof. N. M. Comber (agricultural chemistry); Prof. R. D. Passey (experimental pathology); and Prof. A. V. Williamson (geography). The following appointments have been made in the University: F. A. Leeming, lecturer in the Department of Geography; P. H. Broadhurst, lecturer in the Department of Mining; A. Grounds and L. W. Needham, honorary lecturers in mineral dressing and coal preparation; and J. McFarlane, Hugh Wood Memorial Fellow in the Department of Mining. Donations have been made to the University as follows: renewal by the Worshipful Company of Clothworkers for a further seven years from January 1, 1954, of three grants—£3,000 a year special maintenance grant, £3,000 a year research grant, and £500 a year Dyeing Department research grant—for the Clothworkers' Department; £350 from the British Dyewood Co., Ltd., Glasgow, for postgraduate research in the Department of Colour Chemistry and Dyeing; £600 for 1953–54 from the Medical Research Council for the maintenance of a research worker and the expenses of research in microbiological chemistry in the Department of Biochemistry; £500 for 1953–54 from May and Baker, Ltd., Dagenham, for research in the Department of Pharmacology; £8,455 over three years, allotted through the Board of Trade as a Conditional Aid Project (United States), for research on the wool textile industry, to be conducted in the Department of Economics under the direction of Prof. A. J. Brown; a total of £4,400 for the current session from the National Coal Board, made up principally of grants of £600, £250 and £550, to the Department of Mining for special researches, and £3,000 to the University, this latter being the sessional instalment of a grant promised in 1952 for six years.

Announcements

H.M. The Queen has appointed Lord Cherwell to be a Companion of Honour, on his relinquishing the post of Paymaster-General; Lord Cherwell is returning to his post as professor of experimental philosophy in the University of Oxford, but will continue to be available to the Prime Minister and to the Government on atomic energy questions and other scientific matters.

Dr. O. W. Richards, Reader in Entomology in the Imperial College of Science and Technology, London, has been appointed to the University chair of zoology and applied entomology tenable at that College in succession to Prof. J. W. Munro, who is retiring.

The eighth Dalton Lecture of the Royal Institute of Chemistry will be delivered by Sir John Cockcroft at the Manchester Town Hall on November 27 at 7 p.m., his subject being "The Development of Radiochemistry and Radiation Chemistry". Admittance will be by ticket only. In connexion with the Lecture an exhibition on the measurement, use and application of radioactive substances will be held in the Gas Showrooms (Basement) of the Manchester Town Hall on November 26 (10 a.m.–8 p.m.) and 27 (10 a.m.–9 p.m.). Admission to the exhibition will be free and without ticket. Further details of these events can be obtained from A. Ormrod, Hardman and Holden, Ltd., Manox House, Manchester 10.

Sir George Beilby Memorial Awards, which are considered by administrators representing the Royal Institute of Chemistry, the Society of Chemical Industry and the Institute of Metals, are made to British scientific research workers, preference being given to investigations relating to the special interests of Sir George Beilby, including problems connected with fuel economy, chemical engineering and metallurgy. In general, the awards are granted to younger workers for original investigations done over a period of years. Awards may be made early next year, and the administrators request that their attention be directed, not later than December 31, to outstanding work of the nature indicated. All communications should be addressed to the Convener of the Administrators, Sir George Beilby Memorial Fund, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

Erratum. In the article entitled "Magnetic Properties of the Earth's Interior", in *Nature* of October 31, p. 786, Dr. F. J. Lowes is referred to as being of the University of Liverpool; he is a member of the Department of Geodesy and Geophysics, University of Cambridge.

SUPERCONDUCTIVITY

THE Low Temperature Group of the Physical Society was formed shortly after the Second World War, and since then it has regularly held meetings and discussions on topics of interest to users of low-temperature techniques, both industrial and academic. On October 8 a meeting was held in the Science Museum, London, at which four speakers from different universities presented papers concerned with the problem of superconductivity. Prof. D. M. Newitt was in the chair.

Dr. A. B. Pippard (Cambridge) gave a short account of some of the aims of the current work in the Royal Society Mond Laboratory, Cambridge. The multiplicity of mutually exclusive theories which have been advanced to explain the fundamental mechanism of superconductivity is in his opinion evidence that there is not nearly enough known of the experimental behaviour of superconductors, particularly as regards the finer details of their behaviour. One of the aims of the experimenter should be to construct a physical model of superconductivity which should provide a unified account of the various aspects of the phenomenon and as definite as possible a picture of what must be given a fundamental explanation in terms of the electronic structure of metals. Two important contributions to this end are the theory of F. and H. London of the relation between current and magnetic field, and the two-fluid model of Gorter and Casimir. The former accounts for the almost perfect diamagnetism of a superconductor (Meissner effect), and implies exponential penetration of field to a small depth; the latter correlates the thermodynamic properties with the temperature variation of the depth of penetration. More searching tests of these ideas are now being undertaken. The thermal conductivity and the resistance at very high frequencies both yield information concerning the normal electrons, and the present position seems to be that although the two-fluid model provides a rough explanation of the observations, there is room for improvement, especially as regards the high-frequency resistance. Measurements on thin films and colloidal particles in principle enable the London theory to be tested, but as yet, owing to the extreme delicacy of the experiments, no definite evidence has been obtained. On the other hand, measurements of the absolute magnitude of the penetration depth and of its variation when small amounts of impurity are present suggest that the London theory may be improved by bringing into it the mean free path of the electrons or an analogous parameter. Support for this view comes from studies of the surface energy between normal and superconducting phases, which has been found to be dependent on the mean free path. It is hoped that further work on these lines will eventually permit a better understanding of the nature of the supercurrent and of superconductors in general.

The other speakers discussed more specific topics with which they have been recently concerned. Mr. H. Teague (Bristol) gave an account of the properties of the so-called 'hard' superconductors—vanadium, tantalum and niobium—which are typical of superconductors belonging to Groups 4 and 5 of the Periodic Table. In contrast to tin and other 'soft' superconductors, these have rather broad transitions and the Meissner effect is often very imperfect. There is also a marked tendency for the destruction of diamagnetism to occur at a lower magnetic field-strength than is required to restore resistance. These effects are likely to be caused by inhomogeneities produced either by mechanical working or by interstitial impurity atoms. The former may be removed by prolonged annealing *in vacuo* at a very high temperature, but this rarely removes dissolved impurities; indeed, if the vacuum is not good, additional gaseous impurities may go into solution. Wexler and Corak have demonstrated the deterioration in the behaviour of vanadium resulting from interstitial impurities, while Webber finds no such effect in tantalum. It is therefore likely that, in the latter, mechanical strains are the more important influence. The improvement which vacuum annealing produces in niobium has been studied at Bristol, and the observations support the view that both causes of inhomogeneity are important. It has also been found that some samples after annealing behave very strangely: the resistance drops fairly sharply at the transition temperature for niobium, but not to zero, and the drop is less after more prolonged annealing. It seems likely that individual grains become superconducting but the grain boundaries, which are observed to be broadened by annealing, do not. During the discussion Dr. K. Mendelssohn (Oxford) suggested that the grain boundaries might act as nuclei for the growth of a different crystalline modification which is not a superconductor.

Mr. C. A. Renton (Oxford) discussed the thermal conductivity of superconductors, particularly in the temperature-range below 1° K. According to the two-fluid model of Gorter and Casimir the superconducting electrons have no entropy, and are unable, therefore, to contribute to the conduction of heat, which is effected by the normal electrons and by elastic waves in the ionic lattice. If the scattering of electrons by the lattice is predominantly due to impurities rather than thermal oscillations, the temperature dependence of the electronic contribution is found to agree well with Heisenberg's theory at temperatures not too far below the transition temperature. At lower temperatures Koppe's refinement of the theory appears to be substantiated, and the electronic contribution tends to vanish more rapidly than is predicted by Heisenberg's treatment. At the same time, according to a hypothesis of Hulm, the lattice contribution should increase with lowering of the temperature, since only the normal electrons may be expected to be capable of interacting with the lattice and scattering lattice waves. This expectation is confirmed by the observation that at the lowest temperatures the conductivity in lead, tin and indium varies as T^3, the expected variation for lattice conductivity. The mean free path of the lattice waves is found under these conditions to be of the order of the diameter of the specimen, so that apparently only boundary scattering of lattice waves is effective. In tantalum, on the other hand, the thermal conductivity below 1° K. varies as T^2, which may be accounted for by the hypothesis that there remains even at 0° K. a residuum of normal electrons, insufficient to contribute noticeably to the conductivity, but adequate to scatter lattice waves.

Measurements have also been made on the thermal conductivity in the intermediate state, which may be considerably less than in either of the pure superconducting or normal states; the effect is observed in both longitudinal and transverse fields, and indicates additional scattering processes at the phase boundaries. In the course of the discussion it was mentioned that Laredo at Cambridge has obtained by experiments on impure tin powerful support for the view that lattice conductivity is dominant at the lowest temperatures.

Finally, Prof. G. O. Jones (Queen Mary College, London) described work carried out under his direction by Mr. P. F. Chester on superconductivity at high pressures. The transition temperature is affected by volume changes, and a study of the magnitude of the effect is of interest in connexion with fundamental theories, as those of Fröhlich and Bardeen. By means of Bridgman's crossed knife-edge technique, modified for use at helium temperatures, pressures up to 40,000 atmospheres may be applied to small specimens, the transition of which to superconductivity is observed magnetically. The transition temperature of tin is reduced to about 3° K. from 3·73° K. by the application of 17,000 atmospheres; and although the transition is not very sharp at the high pressure, it is sharp enough to demonstrate that over the majority of the specimen the pressure is nearly constant. So far as the experiments go, there is no evidence for any change in slope of the critical-field curve under pressure. In thallium, contrary to a report by Russian workers, at lower pressures the transition temperature is also reduced by pressure, but only by about one-tenth of the amount found in tin. Of considerable interest is bismuth, for a long time believed to be on the verge of being a superconductor. Hilsch found that bismuth films deposited at 4° K. were superconducting, and it now turns out that massive bismuth is superconducting at pressures greater than 20,000 atmospheres, the transition temperature, 7° K., being nearly constant up to 41,000 atmospheres. Removal of the pressure destroys superconductivity. Since there is a phase-transition in bismuth at room temperature to a more close-packed structure at about 25,000 atmospheres, it seems natural to suppose that it is this modification which becomes superconducting. Other metals being studied are calcium and strontium, which according to Fröhlich's criterion might be expected to become superconducting, but this is not observed up to 40,000 atmospheres.

A. B. PIPPARD

EMPIRICAL RESEARCH IN INDUSTRY

WIDELY varying methods of research for studying the behaviour of individuals and organizations in industry were discussed at an informal week-end gathering held in York during October 2–5 under the auspices of the Acton Society Trust and the York Civic Trust. With backgrounds in the disciplines of anthropology, psychology, sociology, industrial relations, industrial and public administration, operational research, and engineering, twenty-three persons from nineteen university and other research groups met with the common bond that all are actively concerned with research studies of industry.

Two full days of informal discussion were prefaced by a reception, held in the ancient St. Anthony's Hall which now forms part of the Borthwick Institute of Historical Research. The conference was welcomed to York by the chairman of the York Civic Trust, Dr. J. B. Morrell, the chairman of the Acton Society Trust, Prof. A. W. Harvey, and the Lord Mayor of York. On behalf of the visitors, Mr. R. G. Stansfield (Department of Scientific and Industrial Research) said that many research workers, in different parts of Great Britain and working in very different ways, are studying what may be called "the natural history of industry"; often these workers are not well aware of the methods, problems and interests—and sometimes even of the existence—of other workers on related problems. The object of the meeting was to bring together some of these people, so that they could get to know each other and stimulate each other's ideas, with plenty of time for free and frank discussion. York, with its tradition of social pioneering, associated with such names as Seebohm Rowntree and William Temple, was a fitting place for such a conference; and especially in view of Rowntree's pioneer empirical studies of poverty in York, and his association with the early days of the Industrial Health Research Board.

On October 3, Mr. Tom Burns (Edinburgh University Social Science Research Centre) spoke of his research into factory organization. He stated that we are largely at the stage of crude ignorance of what management does; he himself had used the Carlson technique to record how managers spend their time. His findings suggest that in some organizations it would be wrong to talk in terms of vertical communication; the flow of communication is much more 'lateral' than top management usually thinks, and vertical communication is better thought of as 'controlled leaks' up and down from the lateral system. Mr. R. Denerley (Medical Research Council Industrial Psychology Research Group) mentioned six investigations by the Group now under way. The methods used are those of general observation, analysis of factory records, and interviewing techniques; he described some of the work done on investigating and validating various interview techniques. Discussion of these papers took up the second session.

In each subsequent session discussion was prefaced by a single, short paper. Mr. H. Clegg (Fellow of Nuffield College, Oxford) described his methods, as a student of industrial relations, in the study of large-scale organizations. Mr. J. R. Gass (Department of Scientific and Industrial Research), analysing broadly research problems and methods, pointed out that the three previous papers described the use of very different interviewing methods. Each method is appropriate in its own place; his criticism was that the users are unwilling to state the limitations of their method. If between the 'human relations' and 'industrial relations' schools a conflict—a false conflict—seems to be replacing mutual indifference, it is a sign of the impact of mutual relevance of the two approaches. At present, each can be criticized for what it ignores; much American sociology on the changing of habits ignores economic forces and the effect of large-scale organizations external to the factory; the industrial relations school, which studies these large-scale organizations, is interested in the conflicts of power, but tends to ignore the informal structure and personal forces. The link between the two approaches may be found in the study of the conflict for internal power in large-scale organizations.

In a joint contribution, Dr. Alastair Heron and Dr. P. H. Venables (Medical Research Council Unit for Research in Occupational Adaptation) described an investigation of the relation between psychological handicap and occupational adjustment. In this study, the third of a series, relatively objective techniques have been used both in the assessment of psychological handicap and in the evaluation of job-satisfaction and value to the employer. A particular feature of this inquiry was the use of various techniques within the same interview, to indicate the degree of consistency of the data obtained. Mr. Gussmann spoke of the Acton Society Trust's interest in large-scale organizations; this comes under the headings of the internal administrative problems, problems of public control, and problems of the effect on the individual in the organization. From an anthropological background, he is studying five gas-works, of very different sizes, in one particular area, to find out the effects of size of the works. Preliminary results suggest that systematic differences in indices, such as absenteeism, may be due not directly to sheer size but to 'black spots' being harder to control in a larger organization; or to apparently identical jobs in two organizations being inherently different because one organization is big and the other small.

Mr. R. N. Spann (Department of Government and Administration, University of Manchester) discussed the place of the case-study in research and teaching. Case-studies, he pointed out, are so various that the term is of little meaning; they differ enormously in detail of reporting, and whether the description is purely that of a contemporary observer or includes extensive interpretation. By contrast with the abundance of material about how politicians behave, there is a great lack of material about business administration. The most valuable narratives are by people who do not rationalize too much; some accounts of organizations, blinkered by adherence to 'principles of organization', become less and less revealing.

At the final session, Mr. R. G. Stansfield, who acted as chairman during the discussion sessions, summed up the conference. The people for such a conference could not have been found even five years ago; and another sign of the growth and integration of the social sciences in the study of what goes on in industry was the standard of the discussion and constructiveness of the criticism. Thanks were due to Dr. T. E. Chester, of the Acton Society Trust, and his staff for organizing the conference.

In retrospect, the conference seems to have met a real need in bringing together people who did not know of each other's work or—in some cases—each other's existence. It was suggested that social scientists spend much less time than do physical scientists in correspondence between research workers for the exchange of news and views; and those present expressed the future intention of mending their ways. Another live subject linked the scientific method and the problem of recording the results of research. It appeared to emerge that much of the controversy among social scientists about the scientific method (usually in terms of the believed practices of the physical sciences) is misconceived in terms of quantitative and other techniques; the real distinction is between scholars' attitudes of mind, scientific, philosophical, historical and so on. It was suggested that the essential element in the scientific attitude is a distinctive sense of responsibility; including responsibility for seeking out all the relevant data, and for striving to take into consideration all possible alternative interpretations and theories. Especially, the researcher is responsible, in reporting his work, for ensuring that all necessary key details of situation, methods and observations are put on record to enable future workers to compare their results with his and to evaluate his conclusions. In this connexion it was recognized that in accepting this responsibility, the research worker must depend on an equally responsible attitude in the editors of scientific journals.

The interview is the research tool which, in one form or another, is used in all the researches which were described; but while some users appear to take this tool more or less for granted, others are intensely concerned with its techniques and conditions, and it would seem that a whole conference might usefully be devoted to considering knowledge about the interview and its use in the different disciplines of study. Last, but not least, was the sense which kept breaking into the discussion, that the studies which were described, of worker or management behaviour, or of industrial relations, were but stages towards the goal of study of the firm, of the organization, as a going entity; but this study remains for the future to grasp.

R. G. Stansfield

TEACHING OF MECHANICS IN BRITISH UNIVERSITIES

During September a series of informal discussions was held at the Department of Engineering of the University of Cambridge, under the auspices of Prof. J. F. Baker, to consider "the teaching of mechanics, vibrations and control". Representatives were invited from the departments of mechanical engineering of all universities and colleges of university standing in the United Kingdom; in very many cases the head of the department himself elected to attend, so that the fifty or so members of the symposium, as it was called, included a remarkably wide range of engineering teaching experience at this level. A few visitors from large industrial concerns were also invited, to represent the user's point of view.

The nine discussion-periods of an hour and a half each extended from "How much mechanics ought every engineer to know?", through the scope of courses at various levels, to the consideration of teaching techniques, laboratory work and the approach abroad. Each discussion was introduced by a speaker who suggested, as provocatively as he might wish, particular points on which he believed an exchange of views might be valuable. Prof. W. J. Duncan, for example, in opening the discussion of advanced teaching techniques, put in a plea for wider use of the concept of mechanical admittance; and Prof. W. A. Tuplin, of the postgraduate school of applied mechanics in the University of Sheffield, in introducing the subject of advanced and postgraduate courses, wittily described some experiences at this school.

A meeting such as this, which would be a mere commonplace in the United States, is something of an innovation in Britain, and it was most encouraging to find just the same willingness here to admit that there is room for experiment and improvement in many directions. This attitude is particularly important in the branch of engineering under discussion, which has been taught longer than any other and is thus the most likely to lead its teachers to become static and unimaginative or, even worse, complacent about the present methods and courses.

The visiting members of the symposium lived and dined together in Pembroke College, and more than one formal social gathering was arranged during the three days.

It is hoped that the lead given by the organization of this symposium may persuade those in other fields to initiate similar informal meetings, for it was the universal opinion of those attending that the discussions and the personal contacts were both enjoyable and valuable. R. H. MACMILLAN

FOREST DEPARTMENT OF TRINIDAD AND TOBAGO

REPORT FOR 1951

THERE has been a steady progress in forest conservancy in Trinidad and Tobago, as is well revealed in the annual report for the year 1951[*]. The mora forests covering a large area, to which constant allusion was made in reports of a score of years or so ago, are now under conservative exploitation with plans of working coming into force. Reservation of forests is approaching completion; the total area of Crown forests is said to be 617,921 acres, and this is about 50 per cent of the area of the Colony, which has an average length of 50 miles, breadth of 37 miles and a total area of 1,862 square miles. The figures for Tobago are 26 miles by 7½ miles at the widest part and a total area of 116 square miles.

A regulation of the saw-mills in the Colony and the introduction of better equipment to reduce the great waste in conversion were undertaken during the year. Interesting sylvicultural work in connexion with natural regeneration is being undertaken, and an extension of the annual teak-planting area has been sanctioned. The areas under the Forest Department are divided into the Northern and the Southern Divisions. In the latter is the largest forest in the region, the 'Trinity Hills Forest', now to be named "Victoria–Mayaro Reserve", of 129,977 acres. The assistant conservator of forests is in charge of the division, assisted by a forest supervision ranger and forest guards. There is an excellent road system in Trinidad and a ten-year programme for feeder forest roads has been sanctioned, some of these latter to connect with some of the fine new roads of the oil company. Housing for the staff is making progress, and some excellent examples of wooden cottages for forest guards have attracted considerable attention. Climbing plants are giving trouble in the teak plantations, an inevitable pest in tropical forests. Shifting cultivation, with its resultant erosion, and the problem of the squatters in government forests are far from settled, but attempts were being made to settle them in village gardens and also to develop a teak *toungya* scheme. The research branch was renewed in January 1951.

Private forestry is not new in Trinidad, for mahogany plantations were made during 1905–6 by private owners in the hills of the Northern Range, and they now contain trees of timber size with prolific regeneration beneath, which has ousted all other growth. The protection of local fauna has made considerable progress, and there is a small Game Department under the conservator of forests, with wardens. In addition, all forest officers are *ex officio* game wardens, and there are fifty-three honorary game wardens selected from the keen hunters, naturalists and estate owners in the Colony. As is common with some native populations, it is very difficult to enforce a close season, and in this connexion some amendments to the former laws are to be introduced. The revenue from the Department is increasing from sums received from game licences and so forth, and grants from these funds are to be made to the Zoological Society, when this has been incorporated, and to finance a zoo at the Botanical Gardens.

NUFFIELD FOUNDATION

REPORT FOR THE YEAR 1952–53

THE eighth report of the Nuffield Foundation covers the year ending March 31, 1953[*], the fourth of the Foundation's second quinquennial programme, in which allocations against the year's income reached the record total of £713,696. Of this, £319,296 was for research in the United Kingdom—£155,686 for biological research, £54,460 for sociological studies and £109,150 for other scientific work. £26,400 was allocated for research in the British Commonwealth overseas and £36,000 for fellowships and scholarships, and £250,000 for the next five years was promised to the National Corporation for Old People. Under the programme for research on ageing, £25,000 was reserved for a Nuffield gerontological research fellowship, while from the Oliver Bird Fund for rheumatism grants amounting to £24,760 are to be met from the year's income and £18,626 from future income.

Three new grants from the Foundation's uncommitted resources or 'Free Fund' are all in the field of physics: these are to the Department of Mineralogy and Petrology and the Cavendish Laboratory, Cambridge, for a joint study of phase-relations and atomic structure of the feldspar group of minerals; to the Department of Physics of the Royal Cancer Hospital, University of London, for work on the application of physics to diagnostic problems; and a further £20,000 over five years for the appointment of further Nuffield Fellows to Lord Cherwell's low-temperature research group at the Clarendon Laboratory, Oxford. The Foundation has also purchased for £50,000 some special material for research, and £30,000 was allocated to complete the £200,000 promised for the radio-telescope at the University of Manchester.

Of the twenty-six new grants for biological research, seven were for immunological research and six for biophysical and biochemical research, three being in botany. Botany departments are also being assisted in research using micro-organisms, and assistance is being given in comparative endocrinology in the hope that study of the glands of simpler animals may throw light on hormones in the human. The larger grants include £5,250 a year for three years to the Molteno Institute of Biology and Parasitology, Cambridge, for the continuation of Prof. D. Keilin's work on respiratory enzymes; £3,000 a year for five years to the Lister Institute of Preventive Medicine, London, for the study of non-specific defence mechanisms in the early stages of infection; £2,750 a year for five years to the Department of Botany of University College, London, for the establishment of the Nuffield botanic research garden, including research on the physiology of sex in flowering plants; £6,050 for equipment and £1,000 a year for five years to the Department of Biophysics of the College, for work on the permeability of cell membranes and excitable tissues; and a further £10,200 over three years to the Department of Anatomy of the College, for work on the flying-spot microscope and its application to biological research, as well as for the exploration of other electronic techniques. The Research Institute of Plant Physiology, Imperial College of Science and Technology, London, has been promised grants totalling £5,562 over three years towards investigations on the metabolism of the plant polysaccharides and the associated enzyme systems, and £4,294 for its work on gaseous exchanges in leaves and on stomatal mechanism; £8,900 over five years goes to the Department of Experimental Pathology, University of Birmingham, for the immunological study of plant proteins; £8,400 has been provided for the capital and five-year recurrent costs of establishing a radio-carbon dating project in the Sub-Department of Quaternary Research of the Botany School, University of Cambridge; and £2,150 for equipment and £1,300 a year for five years for research in experimental vertebrate embryology in the Anatomy School, University of Cambridge. £6,000 is being provided over five years towards the work on general immunology at the Department of Pathology, University of Cambridge, also supported by the Agricultural Research Council, and £2,000 a year for three years for expansion of the research on the genetics of micro-organisms at the University of Glasgow, while a grant of £1,700 over three years to the Department of Zoology, University of Liverpool, is in support of an investigation of the basic physiology of the endocrine glands in lower vertebrates; £5,600 over three years also goes to the Department of Natural History, University of St. Andrews, for other work in comparative endocrinology, and £5,000 to the Department of Physiology, University of Aberdeen, for work on the bearing of the quantum properties of electromagnetic radiation on the physiology of vision. The Department of Colloid Science, University of Cambridge, has been granted £1,400 for three years for work on the specificity of protein reactions and £800 a year for three years for the investigation of the antigen–antibody reaction by the light-scattering technique, while a personal grant of £3,340 over three years has been made to Prof. J. R. Marrack for his work in the Department of Pathology, University of Cambridge, on antigens and antibodies and the nature of complement and conglutinin. Grants totalling £3,000 over three years for an investigation of the physiology and genetics of sexual reproduction in fungi and of £900 a year for three years for research on the respiratory behaviour of plant tissues have been made to the Department of Botany, University of Oxford.

---

[*] Nuffield Foundation: Report for the Year ended 31 March 1953 (Eighth Report). Pp. 109. (London: Nuffield Foundation, 1953.)

Grants for sociological studies include £22,500 over the next five years to the National Institute of Economic and Social Research, London, and a further £15,000 to the Population Investigation Committee for the publication of its journal, *Population Studies*, and a programme of research including studies of migration, marriage and fertility, both in Britain and in other Commonwealth countries.

From the Oliver Bird Fund a new grant of £2,000 was made to the Department of Physics applied to Medicine, Middlesex Hospital Medical School, London, for physical apparatus for work on the mineral activity of adrenal corticosteroids. Renewed grants were made to the School of Biochemistry, University of Cambridge, for work on the isolation and purification of the adrenocorticotropic hormone (£4,100); to the Department of Biomolecular Structure, University of Leeds, for its collaboration with the Rheumatism Research Centre, University of Manchester (£1,000); and to the Dyson Perrins Laboratory, University of Oxford, for attempts at the total synthesis of cortisone. The £37,000 allocated for research into practical problems includes £36,000 for establishing a unit for functional research in building design. Miscellaneous grants include £4,000 a year for three years to the Oxford Regional Hospital Board for a study of the relation of physique to mental and nervous disorders, £1,200 towards an expedition to study the blood-groups and search for the sickle-cell trait in the Andaman Islanders, £1,000 a year for three years to the Y.W.C.A. for courses in tropical rural welfare for women from the Commonwealth and under-developed countries visiting Britain, and £1,500 to the Department of Anatomy, Charing Cross Hospital Medical School, London, for a study of the development of the human placenta.

New grants for research overseas within the Commonwealth include £1,200 a year for three years to further the expansion of the work of the Australian and New Zealand Association for the Advancement of Science, £2,000 to the University of Cape Town for the purchase of spectrographic equipment for the Department of Geology, £1,000 to the Transvaal Museum for a mobile entomological laboratory and £12,000 towards the capital cost of the metabolic unit to be established at Kampala by the Medical Research Council and the Government of Uganda for the study of infantile malnutrition and particularly the prevention of kwashiorkor.

During the year fifty-four Nuffield Fellows, Scholars and Bursars (including twenty-seven travelling fellows from the Dominions) were appointed under the Foundation's various schemes. More interest was taken in the dental fellowships and scholarships scheme, while the scheme of travelling scholarships for farmers of the United Kingdom operated very satisfactorily, and the Foundation decided to institute a number of more junior awards, namely, farming bursaries, tenable for one to three months for travel in the United Kingdom and, for a few weeks, in a Scandinavian country. The biological scholarships and bursaries scheme is now interesting a wider and stronger field of applicants. Under the scheme of lectureships and special grants for eminent scientists or scholars, some Canadians and one Australian visited the United Kingdom, and the United Kingdom sent two to Australia, one to South Africa, two to Canada and the United States, and one to Scandinavia.

A NEW PHENOMENON IN TIME JUDGMENT

By PROF JOHN COHEN, C. E. M. HANSEL and J. D. SYLVESTER

Department of Psychology, University of Manchester

THE *tau* effect, demonstrated by Helson and King[1] in 1931, may be illustrated by the following example. If three points are marked off on the observer's skin and the interval of time between stimulating the second and third points is greater than that between the first and second, the observer reports that the distance between the second and third points is greater than that between the first and second, though in fact it may be equal or less. Geldreich[2] has devised an apparatus whereby this effect may be shown to occur with visual stimuli. These phenomena show a dependence of judgments of distances between stimuli on the time intervals separating them. The experiment to be described was designed to test quantitatively the hypothesis that judgments of temporal intervals between visual stimuli are similarly dependent on their spatial relations.

The subject sat in a dark room and observed in front of him a repeated succession of three equal flashes of light set horizontally. Each cycle of three flashes was repeated after an interval of 5/3 of the total cycle. By adjusting a lever he was able to control the timing of the flash of the centre light over a range varying from simultaneous with the first light to simultaneous with the third. That is, if the interval of time between lights 1 and 2 is designated t_1, and that between lights 2 and 3 designated t_2, he adjusted the lever until he judged t_1 as equal to t_2. The distances separating the lights could be varied by the experimenter. The shorter of the two distances remained constant at one foot and the longer distance was varied so as to give a ratio ranging from 1 : 10 to 10 : 1. If the first distance is called d_1 and the second d_2, the ratio d_2/d_1 varied from 1/10 to 10/1. The cycle of lights was repeated continuously until the subject had completed his adjustment, which he indicated by pressing a button.

Subjects made four judgments at each distance ratio: one pair with the shorter distance first, one pair with the longer distance first, one of each pair being presented with the right to left direction reversed.

In the accompanying table we show in columns (i) and (ii) the mean values of t_2/t_1, for each ratio of d_2/d_1, when $T = (t_1 + t_2) = 1·4$ sec. In columns (iii) and (iv) the mean values of t_1 and its standard deviation are given respectively. In column (v) we show the values of t_1 corrected for time error. Time errors are effects which occur in judgments involving successive presentations of stimuli. In this case a correction is made by multiplying values of t_1 by a constant derived from the 1 : 1 ratio of distances. Column (vi) gives an estimate of the percentage effect of the phenomenon.

Similar effects were obtained with $T = 0·6$ sec. and $T = 6·4$ sec. Within this range of T (0·6–6·4) the effect tends to diminish as T increases. The effect is significant at all values so far measured.

Mean results for 10 subjects when $T = (t_1 + t_2) = 1·4$ sec.

(i)	(ii)	(iii)	(iv)	(v)	(vi)
$\frac{d_2}{d_1}$	$\frac{t_2}{t_1}$	t_1 (sec.)	σ_{t_1} (sec.)	t_1' (sec.)	$\frac{t_1'-t_1'}{t_1'}$ .100 (percentage)
1/10	1·15	0·65	0·059	0·60	−12·1
1/8	1·22	0·63	0·058	0·64	−18·8
1/6	1·26	0·62	0·057	0·66	−12·1
1/5	1·22	0·63	0·061	0·65	−15·4
1/4	1·30	0·61	0·071	0·64	−18·7
1/3	1·37	0·59	0·080	0·60	−25·8
1/2	1·19	0·64	0·014	0·67	− 9·0
1/1	1·10	0·67	0·093	0·70	0·0
2/1	0·92	0·73	0·034	0·76	15·8
3/1	0·89	0·74	0·035	0·77	18·2
4/1	0·89	0·74	0·051	0·77	18·2
5/1	0·87	0·75	0·046	0·80	25·0
6/1	0·87	0·75	0·010	0·78	20·5
8/1	0·94	0·73	0·062	0·73	8·2
10/1	0·89	0·74	0·048	0·75	13·3

It may be seen from column (vi) in this table that comparative judgments of two successive time intervals delimited by successive flashes of light are influenced by the spatial relationships of these flashes. Although the figures given in the table relate to the means for ten subjects, repeated trials with single subjects show that intra-individual variation is less than inter-individual variation. This statement is based on 6–20 trials by different subjects at each distance ratio. The standard deviations for the individual subjects range from 0·022 to 0·067 for different distance ratios when $T = 1·4$ sec.

The effect is such that when the observer is adjusting the time intervals so that they appear equal he makes the time interval between the two flashes spaced farther apart shorter than the time interval between the two flashes closer together. The phenomenon that thus emerges is that when three flashes of light are successively presented and separated by equal temporal intervals, one temporal interval will seem longer as the relative distance between the corresponding flashes increases. We propose to designate this phenomenon as the *kappa* effect to distinguish it from the *tau* effect. A measure of this effect is given in column (vi). When, for example, d_2/d_1 is 1/10 there is a 12 per cent underestimation of t_1, and when d_2/d_1 is 10/1 there is a 13 per cent over-estimation.

A brief reference may be made to two further conclusions which will be more fully described elsewhere: (*a*) order of presentation; and (*b*) effect of visual angle. The *kappa* effect is uninfluenced by the order in which the distances are presented. This fact is in conflict with the Gestalt theory of perceptual transposition.

The total visual angle subtended by the display in the experiment reported varies with the distance ratio being measured, since the shorter distance is constant at 1 ft. The decline in the effect at the extreme ratios seems to be due to the increase in visual angle. Experiments in progress show that when the distance ratio is held constant the *kappa* effect increases with decrease in the visual angle.

It would seem from the two phenomena that the spatial and temporal components of the space–time events about which judgments are made are psychologically interdependent. It may be asked whether the spatial element as such is an essential feature of this type of temporal phenomenon and whether a delimitation of the time intervals by other kinds of non-spatial stimuli such as auditory pitch might produce similar effects. If so, it would be possible to employ temporal judgments as a probe in the general study of inter-sensory phenomena, a subject which is receiving increasing attention. [Oct. 5.

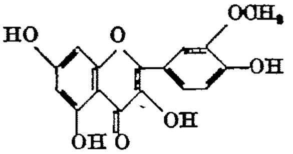
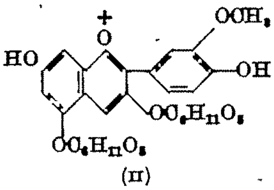
BIOGENESIS OF FLAVONOIDS IN *CHLAMYDOMONAS EUGAMETOS*

By Prof. A. J. BIRCH*, F. W. DONOVAN*
and Dr. F. MOEWUS†
University of Sydney

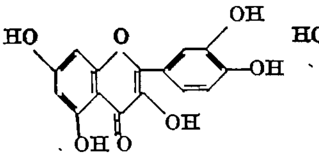
A NUMBER of theories have been advanced to explain the biogenesis of flavonoid and anthocyanin pigments in plants[1,2], the most fundamental of which, due to Robinson, postulates a $C_6—C_3—C_6$ linkage ultimately due to carbohydrate units. Opinions are very varied on the origins of points of detail in the structures, for example, on how the various states of oxidation are attained and whether flavonoids precede anthocyanins in the chain of biogenesis. Despite much work on the genetics of flower colour[3], little that is conclusive has emerged, except the demonstration that the processes are gene-controlled, and that flavonoids and anthocyanins are derived from the same precursors, if not in sequence. The chief difficulties with this work are the extreme complexity both of the genetic factors and of the pigment mixtures, and in order to provide evidence of much value most of it would need to be repeated using modern chemical techniques.



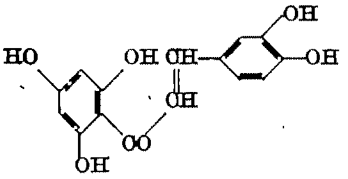
(I)



(II)



(III)



(IV)

A much more amenable organism for biochemical study is found among the lower plants, since the green alga *Chlamydomonas eugametos* uses the flavonoid isorhamnetin (I) and the anthocyanin peonin (II) as sex hormones[4]. Briefly, a diœcious culture transferred from agar to water, if illuminated, undergoes a series of changes, developing flagellæ, motility and ability to copulate. All these stages are hormone-controlled, the hormones required for sex-determination and therefore ultimately for copulation being, for the male peonin, for the female isorhamnetin[4]. During 1939–51 a large number of mutation experiments were carried out, using X-rays, radium, ultra-sound, chemical compounds and temperature shocks. From these were obtained thirty-seven mutants which were genetically female but which were not able to copulate with male gametes. However, they did so on the addition of traces of isorhamnetin. Of these mutants, twenty-six were rendered capable of copulation when given quercetin (III), the remaining eleven reacting only to isorhamnetin. Some sixty other flavonoids tested were without activity. Kuhn and Loew[5] succeeded in isolating quercetin from one of the eleven mutants, and we have further identified the substance from this mutant by the use of paper chromatography; from another female mutant (*irha*$^{+++}$) Kuhn and Loew isolated isorhamnetin. The twenty-six mutants can obviously convert quercetin to isorhamnetin; the other eleven cannot.

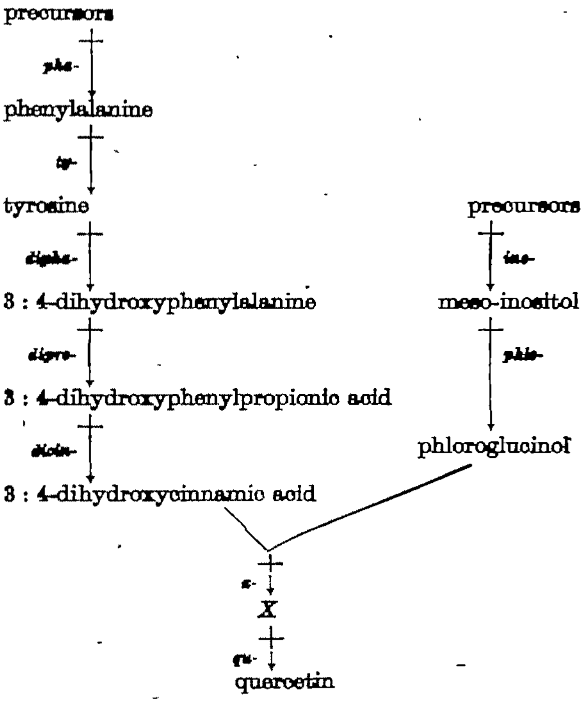
There was at this stage no indication of the number of steps, since many of the mutants from different mutation experiments could be, and were found to be, biochemically identical.

These results can be briefly summarized: precursors (unknown number of stages, twenty-six mutants) → quercetin (III) → isorhamnetin (I) (unknown number of stages, eleven mutants).

Substitution experiments were then carried out with the twenty-six mutants. The mutants were kept in a solution of the substance to be tested (concentration 10^{-5}–10^{-9}) for four hours, and a drop was then mixed with normal male gametes. Immediate copulation is indicated in Table 1 by a (+) sign. This presumably indicates the ability of the mutant to produce quercetin from the test substance. Table 1 shows twenty-five mutants; the twenty-sixth is a double mutant (*dicin-*^{4}*-phlo-*^{3}). The concentration *c* is the lowest limit for observable activity.

Among compounds found to be inactive were: 3- and 4-hydroxycinnamic acid, 4-hydroxy-3-methoxycinnamic acid, *cis*- and *trans*-cinnamic acid, phenylpropionic acid, 3- and 4-hydroxyphenylpyruvic acid, phenylpyruvic acid, phenyllactic acid, 3 : 4-dihydroxybenzoic acid, methylphloroglucinol, phloroacetophenone, epiinositol and pyruvic acid. It is noteworthy that (−)- and (±)-phenylalanine and (+)- and (±)-tyrosine have the same activity to an order of ten, which is the limit of sensitivity of the test.

If we can assume that the substances are active by virtue of their transformation to quercetin, and not *per se*, then the following scheme of biogenesis is indicated:



---

* Department of Organic Chemistry.

† Botany School.

Table 1

qu-Mutants (twenty-five ; arbitrary numbers)	3, 4, 7, 13, 19, 23	2, 10, 16	1, 15, 21, 24	5	12, 20, 22	8, 11, 17	6, 9, 14	18, 25
Quercetin ($c = 10^{-10}$)	+	+	+	+	+	+	+	+
3,4, diOH Cinnamic ($c = 10^{-6}$)	−	+	+	+	+	+	−	−
3,4, diOH Propionic ($c = 10^{-7}$)	−	−	+	+	+	+	−	−
3,4, diOH Phenylalanine ($c = 10^{-7}$)	−	−	−	+	+	+	−	−
Tyrosine (+) and (±) ($c = 10^{-6}$)	−	−	−	−	+	+	−	−
Phenylalanine (−) and (±) ($c = 10^{-6}$)	−	−	−	−	−	+	−	−
Phloroglucinol ($c = 10^{-6}$)	−	−	−	−	−	−	+	+
m-Inositol ($c = 10^{-7}$)	−	−	−	−	−	−	−	+

Neither of the mutants on the phloroglucinol side of X is affected by any of the substances on the 3 : 4-dihydroxycinnamic acid side, and vice versa. The nature of X is at present unknown; but the reaction would suggest that it is the chalcone (IV) or the corresponding flavanone or flavone.

If this scheme is correct, then the *dicin*-mutant should accumulate 3 : 4-dihydroxyphenylpropionic acid, the *x*-mutant phloroglucinol and 3 : 4-dihydroxycinnamic acid and so forth. This has several consequences. One is that any pair of mutants on the same branch of the synthetic scheme should be capable of copulation if mixed, since one or other will be capable of supplying a substance required by the other mutant for completion of the quercetin synthesis. In fact, a mixture of the *ino*- and *phlo*-mutants copulated with male gametes, as did all mixtures of *dicin*-, *dipro*-, *dipha*-, *ty*- and *pha*-, but not a mixture of this group with the preceding one. Another consequence is that the accumulated substances would be detectable biologically and chemically, for example, a centrifugate from the *ty*-mutant should contain phenylalanine. The copulation tests on such centrifugates bears this out (Table 2), the solutions from each mutant activating all the preceding ones in the series.

Table 2

Centrifugate solution from	Mutant test cells								
	qu-	*x*-	*dicin*-	*dipro*-	*dipha*-	*ty*-	*pha*-	*phlo*-	*ino*-
Quercetin	+	+	+	+	+	+	+	+	+
qu-Mutant (4)	−	+	+	+	+	+	+	+	+
x-Mutant (3)	−	−	+	+	+	+	+	+	+
dicin- ,,	−	−	−	+	+	+	+	−	−
dipro- ,,	−	−	−	−	+	+	+	−	−
dipha- ,,	−	−	−	−	−	+	+	−	−
ty- ,,	−	−	−	−	−	−	+	−	−
pha- ,,	−	−	−	−	−	−	−	−	−
phlo- ,,	−	−	−	−	−	−	−	−	+
ino- ,,	−	−	−	−	−	−	−	−	−

Of the twenty-five mutants, fourteen are activated by the C_6—C_3 compounds, five by the C_6 and the remaining six by the C_6—C_3—C_6 compound quercetin. By mixing these six mutants (3, 4, 7, 13, 19, 23) in pairs (Table 3) it is possible to show that they represent, in fact, only two biochemical types: 3, 7, 19 and 4, 13, 23, the former the *x*-mutant, the latter the *qu*-mutant, since the centrifugate from the *qu*-mutant activates the *x*-mutant and not vice versa (Table 2).

Table 3

	3	7	19	4	13	23
3		−	−	+	+	+
7	−		−	+	+	+
19	−	−		+	+	+
4	+	+	+		−	−
13	+	+	+	−		−
23	+	+	+	−	−	

Chemical experiments have also been instituted to confirm the presence of the accumulated substances. The mutant was grown on agar (equivalent to about ten Petri dishes) and extracted with alcohol. The evaporated solution was then examined by standard methods of paper chromatography using downward displacement. The solvents used were: (A) butanol–acetic acid–water (4 : 1 : 5) and (B) *m*-cresol–acetic acid–water (25 : 1 : 24), and in all cases the suspected substance was run on the same chromatogram and gave a spot of identical R_F. These values were (18–20°): phenylalanine, A, 0·60, B, 0·88; tyrosine, A, 0·39, B, 0·40; 3 : 4-dihydroxyphenylalanine, A, 0·22, B, 0·15; 3 : 4-dihydroxyphenylpropionic acid, A, 0·89, B, 0·65; 3 : 4-dihydroxycinnamic acid, A, 0·87, B, 0·50; phloroglucinol, A, 0·75, B, 0·19; inositol, A, 0·07.

The spots were detected by appropriate reagents, for example, silver nitrate for the catechol derivatives, ninhydrin for the amino-acids. 3 : 4-Dihydroxycinnamic acid fluoresced in ultra-violet light, and phloroglucinol did so in presence of ammonia. Inositol was detected by spraying with silver nitrate and heating to 105°; owing to the low R_F value, one chromatogram was allowed to drip off the paper; the distance travelled was still the same as a known mesoinositol spot.

All steps except two represent known or probable biochemical transformations; one step of great interest is the conversion of mesoinositol to phloroglucinol, which has been suspected before[6]. The other unknown stage is the apparent direct deamination of 3 : 4-dihydroxyphenylalanine to 3 : 4-dihydroxyphenylpropionic acid. It is possible that a mutant has been missed which produced 3 : 4-dihydroxyphenylpyruvic acid, but we have so far been unable to prepare this substance in a state of purity and it has not been detected in a mutant. A direct deamination by a reduction process is not improbable from the point of view of chemical mechanisms if the substrate involved is the conjugate acid from the amino group. A similar deamination in *Chlamydomonas* has also been observed in another connexion[7].

Full details of this work, and its bearing on the biosynthesis of other compounds containing C_6—C_3 units, will be discussed elsewhere. It may be remarked, however, that the intervention of phloroglucinol raises considerable difficulties in a general theory of the biogenesis of compounds containing less oxygen in this ring, and alternative theories are possible[8].

We are grateful to Timbrol, Ltd., the Dunlop Rubber Co., and the Rockefeller Foundation for

financial assistance, and to Mrs. L. Moewus for growing the cultures employed in this work.

RELATION OF CHEMICAL STRUCTURE TO IRRITANT RESPONSES IN MARINE FISH

By PROF. ROBERT W. HIATT, PROF. JOHN J. NAUGHTON and PROF. DONALD C. MATTHEWS

University of Hawaii

FOR a variety of reasons, there has been an increasing demand for chemicals capable of repelling fish. In an attempt to fill this need, we have made a search for the most effective irritant chemicals for marine fish, and incidentally for the relationships of chemical structure to irritant responses. In a recent paper[1] we reported preliminary results of the study; but too few data were available at that time to assert these relationships with any degree of certainty. Now that more than five hundred selected compounds have been tested, certain relationships have become increasingly evident, and this brief account, with selected supporting data, serves to summarize them by presenting certain hypotheses which provide the basis for detailed analyses which will appear at a later date. It is hoped that this condensation will aid other workers conducting similar investigations by indicating those molecular characteristics which appear most active in inducing irritant responses in fish, particularly those mediated through the common chemical sense[2].

Hitherto, only scattered information on this subject had been secured when fish were accidentally or incidentally affected by insecticides[3] or pollutants[4], until an extensive search was made during the Second World War for chemicals repellent to sharks[5,6]. Our studies show that chemicals found most active in the latter tests are of little use as repellents for bony fish. Thus, this subject has been but barely touched.

A full account of the methods used, means by which chemicals were selected and certain ancillary considerations of the distribution of reacting substances in sea water were presented in our earlier paper[1]. Briefly, tests were conducted in aquaria with a capacity of 50 litres, in which a small school of four or five fish (*Kuhlia sandvicensis*) was exposed to chemicals dispersed or dissolved in sea water. The usual span of observation was limited to two minutes, because the prime objective was to discover rapidly-acting irritants. Responses varied from mild to severe, and upon a background of many observations these reactions were rated as slight, medium or violent. It was not feasible to make finer distinctions. Naturally, different types of responses were evoked by different irritant chemicals. For example, nearly all irritants attacking the common chemical sense produced excitation, body shaking and rather violent swimming. Substances reacting as respiratory poisons induced gulping, swimming at the surface and generally depressed activity. Certain substances evoked unusual responses such as tetanic and flaccid paralysis, operculum and fin distension, disorientation, convulsions, etc. These reactions we assume to be the result of very intense stimulation of the sensory receptors. Some substances which *a priori* might be expected to exhibit a degree of irritant action such as stenches (sulphides and mercaptans), organic cyanides (nitriles) and narcotics (aliphatic alcohols) had little or no visible effect during the brief period of the test. Although we discerned a number of rather discrete responses to different compounds, it was not always possible to define precisely symptoms characteristic of a particular compound or of a group of organic homologues, because of the widespread receptor system for the common chemical sense, and because of the interdependence of life processes.

In the course of our experiments it soon became apparent that certain types of chemicals possessed the irritant properties sought. In general, lachrymators and skin irritants were found to be the most effective of the physiologically active chemicals tested. Certain insecticides of the irritant type (pyrethrins) were moderately effective, as were respiratory poisons (for example, cyanide ion). Cyanide ions are known to inhibit respiratory enzymes, and the extensive work reported by Dixon and Needham[7] indicates that lachrymators and skin irritants operate through the inhibition of thiol groups in enzymatic systems. Of importance is the fact that the activity of the more highly irritant chemicals persists to a concentration which is still within the order of magnitude of that required to inhibit such enzymes (0·1 part per million).

Certain aspects of our experiments must be clarified, lest our results appear inconsistent in details with others reported in different circumstances. First, the two-minute span of each experiment eliminates from consideration such reagents as the mercuric ion which produces a mercaptide with the —SH group and does impart irritation to fish, but only after a much longer period[8]. Second, the most active alkylating agents, also inhibitors of the thiol groups, easily and rapidly hydrolyse and thus may be destroyed before reaching

Chemical	Dilution in parts per million				
	10·0	1·0	0·1	0·05	0·01
Phenacyl chloride	+++	+++	++	+

Chlorine	+++	+			

+++ Indicates violent irritant activity; ++ indicates moderate irritant activity; + indicates slight irritant activity; and – indicates no irritant activity the sensory receptors. Such reagents, protected by dispersion in mineral oil, were nearly always an order of magnitude more active as irritants (powers of 10 in our dilution series) than when unprotected. Third, lipoid and aqueous solubility of irritant chemicals would radically modify the irritant qualities expected on the basis of other properties of the molecules.

Respiratory Poisons

Certain substances known to inhibit respiratory enzymes by attacking groups other than thiols were found rather active as irritants. Notable among these was the cyanide ion (see table), a well-known respiratory enzyme poison, which elicited surface swimming, gulping and depressed activity generally, precisely the type of behaviour expected in response to oxygen deficiency. Likewise, organic thiocyanates which are reputed to liberate hydrogen cyanide in animal tissue[9,10] were found to possess a rather uniformly high degree of irritant activity.

Thiol Inhibitors

Chemicals which inhibit thiol groups are sometimes divided into three categories[11]: (1) mercaptide-forming agents such as heavy metals and metalloids which displace the hydrogen of the thiol; (2) oxidizing agents which oxidize sulphydryl groups to disulphides; and (3) alkylating agents which replace the hydrogen of the thiol to form alkylated compounds. We consider all these mechanisms to be similar in that they involve either a complete loss of electrons (oxidation), or a replacement of a slightly electronegative hydrogen atom by a more electronegative atom (heavy metal or carbon of the alkylating group) with a consequent loss in the share of electrons held by the sulphur atom of the thiol group, that is, oxidation of the sulphur. We are also convinced that it is more than mere coincidence that these are precisely the substances which have been found to be most active as general irritants to fish. Chemical groups which impart the most irritant quality to molecules of this type are aliphatic and aromatic nitro compounds, nitroso compounds, halogenated substances with the halogen *alpha* to a carbonyl or phenyl group, halogens linked to a metal in metallo-organics, disulphides, quinones and compounds with a carbonyl conjugated to a double bond. It is noteworthy that many of these are considered to be typical alkylating agents[11]; but more significant is the fact that these are the types of molecules which are found by polarography to be reducible at the dropping mercury electrode, that is, they are oxidizing agents[12].

In dealing with irritant chemicals which are oxidizing agents, one would naturally try to relate irritant power to oxidizing potential. Such relationships were found to apply in a few cases where a series of very similar compounds were compared (for example, the halogens); but general correlations were not found or were rather tenuous. Correlations of this sort would be very difficult to make because of the lack of oxidation potentials for organic substances measured under conditions that would in any way be comparable to the lipoidal and *p*H conditions under which these chemicals react physiologically. Polarographic data, while helpful, are usually obtained for aqueous – organic solvent mixtures at a variety of *p*H values.

Of importance, too, is that substitution of electrophilic or electrophobic groups on the molecules affects the irritant activity to about the same extent as it is known to affect the reducibility of the reactant molecule, that is, its oxidizing power. Removal of electrons from the reactive groups by the inductive effect[13] of electrophilic or electron-attracting groups ($—NO_2$, —halogen), or by the similar electrophilic resonance or tautomeric effect of certain groups ($—NO_2$, —COOH), enhances the irritant activity of the group because it also increases the ease of reduction. Groups which exhibit an electrophobic character (for example, methyl) have an opposite effect. Caution must be exercised in adding electrophilic groups to augment irritant activity towards fishes, because this frequently enhances the hydrolysability of the compound.

In the accompanying table are shown a few selected examples of the irritant activity of chemicals which we believe inhibit the sulphydryl group through their action as alkylating or oxidizing agents. The action of mercaptide-forming agents, as already mentioned, is too sluggish to exhibit irritation within the brief span of the tests.

It was surprising that, among oxidizing agents, little or no irritant power seemed inherent in organic and inorganic peroxides within the range of concentrations normally used in these tests. Because of the great dilutions used, these substances probably reacted with oxidizable impurities present in sea water, and thus were consumed prior to contact with the fish. In support of this view, benzoyl peroxide, protected by mineral oil, imparted pronounced irritant activity. Moreover, hydrogen peroxide at higher concentrations (100·0 parts per million) proved to be a very effective irritant.

In summary, based on our results so far, we believe that the most violent irritant responses mediated through the common chemical sense of fish are stimulated by inhibition of sulphydryl groups of one or more enzymes associated with the sensory receptors. Based on this hypothesis, tests are being continued on many variations of molecules which serve as thiol inhibitors to learn the effects of substituents. As a corollary, combinations of chemicals likely to have synergistic action are being tested. For all highly active compounds, various methods of suspension in aqueous media are being tried to ascertain the best vehicle for conducting the irritant substance to the site of action prior to the advent of hydrolysis or of some other vicarious chemical reaction with sea water.

These studies were aided by a contract between the Office of Naval Research, U.S. Department of the Navy, and the University of Hawaii (NR 160-165).

Qualitative Organic Micro-analysis based on Physical Constants: Identification of Amino-Acids

THE usual way of identifying organic compounds consists in preparing a crystalline derivative and determining its melting temperature. Such preparation requires at least 50 mgm. of material. Compounds not showing distinctive properties (such as hydrocarbons), or only slightly reactive, also those decomposed by the reagents, do not easily yield characteristic derivatives.

Physical constants like density, solubility, refractive indices, melting and boiling points have already been used for identifying such organic compounds. In recent years, some of these constants have been used in special circumstances on the micro scale for identification purposes, as in biochemistry and atomic researches. The Linderstrøm-Lang density determination is well known for its accuracy[1]. More recently, methods based on melting points and refractive indices have been developed by A. Kofler and L. Kofler[2]. By these methods, it is possible, from observations made on one crystal alone, to make deductions about the purity of a compound and the nature of any contamination, and also to carry out a quantitative thermal micro-analysis. Eutectics play a big part in these methods, and as these eutectic mixtures always melt at lower temperature than either of the two partners, the observation of the beginning of melting gives precise results. Some of these eutectics melt at room temperature, and by proper selection they can be used to identify substances of the type mentioned above, or those decomposed by heating.

The amino-acids are a class of compounds of much present interest. They are very reactive, but rather fragile when heated. A great number[3] of their derivatives are known, but there are some gaps. Several of these derivatives also decompose on heating and are therefore useless for identification. Moreover, amino-acids are expensive, and where testing is frequent, the price of each determination has to be considered; a method requiring only one crystal is then preferable to one needing 50 mgm.

The density of twenty of these acids[4] has already been determined, but the results do not show great differences for closely related individuals; refractive indices are given in the literature for only three amino-acids[4]; no eutectic has been studied hitherto or used for the purpose of identification; solubility and rotatory powers[5] are extensively used, but conditions are not standardized, so that these are also useless for identification.

Table 2. REFRACTIVE INDICES OF AMINO-ACIDS (ONE CRYSTAL)

α-alanine	1·515	1·575	0·060	1·424	25·91	26·69

The present investigation has been developed with the view of providing data on eutectics and the refractive indices of amino-acids that can serve for rapid and easy identification of these compounds, either as crystals or as solute. These can be used for checking chromatographic separations on ion exchangers, where it is never certain that the isolated fraction effectively consists of only one known compound and no other. The techniques adopted here are those described in the literature[1,2,6]. Table 1 includes a short selection of results which can be recommended for identification purposes.

The refractive indices of these acids have been determined by an immersion method[7], using the crystals as they are deposited on the microscope slide (Table 2). These crystals are grown identically and all show the same aspect whatever their origin. The crystal is at first placed under the microscope between crossed nicols (parallel light, known temperature and filtered light) in the extinction position in a dark field. The analyser is taken away and the first index is determined in that position. Then the crystal is turned through 90° and the second index is determined. These two indices are arbitrary and called $n'p$ and $n'g$. This technique needs no special knowledge, and gives characteristic data that can be used for identification of these acids using even only one crystal recovered from a solution. The accuracy of the refractive index in this work is ± 0·001. Determination takes about one minute.

Very strong structural influences can be demonstrated by the melting point of binary mixtures of

Table 1. BINARY EUTECTICS

Amino-acids	Eutectic partner	Melting point (° C.)	Amino-acids	Eutectic partner	Melting point (° C.)
glycocol	β-alanine	166–168	*dl*-norleucine	tartaric acid	118
	ε-amino-caproic acid	193–195		malonic acid	< 90
ε-amino-caproic acid	β-alanine	169		phthalic acid	111–115
	dl-norleucine	188		aspirine	115–120
	dl-isoleucine	193–195		pyrogallol	99–100
	dl-aspartic acid	145–148	*dl*-aspartic acid	malonic acid	99–102
	l(+)-glutamic acid	154–156		tartaric acid	141–142
	dl-valine	198	*l*(+)-glutamic acid	tartaric acid	130
	dl-β-phenylalanine	186		malonic acid	< 90
	l(−)-tyrosine	190–191		ascorbic acid	159–160
dl-leucine	glucose	138–139	*dl*-β-phenylalanine	malonic acid	105
	hippuric acid	173–174		O-hydroxy benzoic acid	139–140
	α-chloro-acetamide	109–110		thiourea	163–166

	hippuric acid	168–169		malonic acid	119–121
	α-chloro-acetamide	< 100		tartaric acid	156

these acids as well as by the refractive indices. The method is therefore useful for identification of these substances. It can be extended to other groups of rganic substances as a qualitative method of functional organic micro-analysis. These determinations, taking so little time and so little material, might be introduced as a general means of identification of compounds in the classical qualitative organic analysis of mixtures (Staudinger, Shriner, Fuson and Kamm) instead of the usual preparation of derivatives.

Quantitative aspects of this work are now being tudied by us.

These investigations have been supported by a grant from the Belgian F.N.R.S. Institute.

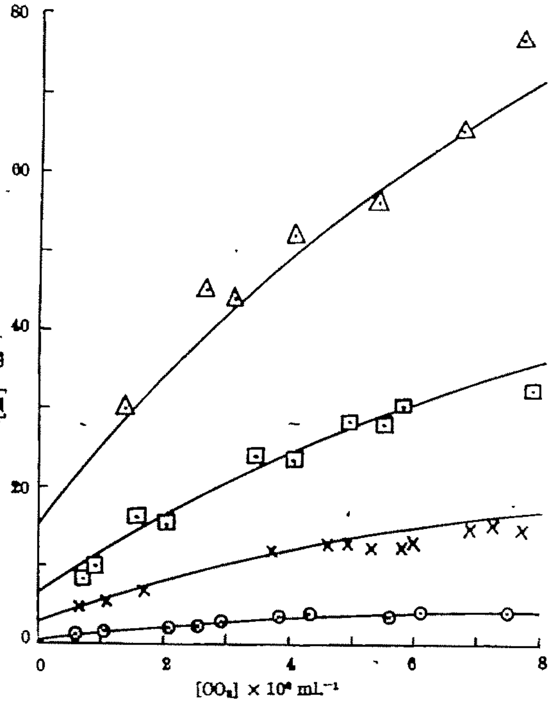
Kinetics of the Formation of Polypeptides from N-Carboxy-α-amino-acid Anhydrides

This well-known synthesis of polypeptides from N-carboxy-α-amino-acid anhydrides has been extensively used recently for preparative purposes, but the mechanism of the reaction has received comparatively little attention. The only publication dealing with the kinetics seems to be that of Waley and Watson[1], who studied the polymerization of sarcosine N-carbonic anhydride. These authors concluded that the reaction mechanism is surprisingly complicated; the order with respect to monomer appeared to be less than 1 initially, but approached unity towards the end of the reaction. Further, when preformed polymer was used as initiator, the dependence of the rate on initiator concentration was represented by a power of the latter lying between 1 and 2.

In carrying out a more extensive study of these polymerizations we have recently had occasion to repeat some of the work of Waley and Watson; this has resulted in our finding a hitherto unsuspected feature of the reaction which necessitates a new approach to the problem. Working with a constant-pressure apparatus, we have found that the reaction in nitrobenzene is strictly first-order in monomer concentration throughout. It is, however, strongly catalysed by carbon dioxide. The accompanying diagram shows the variation of the first-order rate coefficient $(-d \log[M]/dt)$ with carbon dioxide concentration at 25°, for a series of different initiator concentrations. We have shown that there is a definite uncatalysed reaction at zero carbon dioxide concentration. Since Waley and Watson worked with a constant-volume apparatus, the steadily increasing pressure would result in a corresponding increase in rate constant in their experiments, leading to the apparent change in the order with respect to monomer. We find that the order in initiator concentration is very close to 2, and further that the reaction has a negative temperature coefficient as noticed by Waley and Watson.



Catalysis by carbon dioxide of the polymerization of sarcosine N-carbonic anhydride in nitrobenzene at 25°.
△, $[X]_0 = 1\cdot58 \times 10^{-2}$ mol. l.$^{-1}$. ×, $[X]_0 = 0\cdot75 \times 10^{-2}$ mol l.$^{-1}$.
⊡, $[X]_0 = 1\cdot09 \times 10^{-2}$ mol. l.$^{-1}$. ○, $[X]_0 = 0\cdot37 \times 10^{-2}$ mol. l.$^{-1}$.
The continuous curves are calculated from equation (3) using the following values of the constants: $K_1 = 60\cdot6$ mol.$^{-2}$ l.^{2}; $Kk_1 = 5\cdot8 \times 10^4$ mol.$^{-2}$ l.^{2} min.$^{-1}$; $Kk_2\sqrt{K_1K_2} = 1\cdot6 \times 10^6$ mol.$^{-5/2}$ l.$^{5/2}$ min.$^{-1}$; $Kk_3K_1K_2 = 3\cdot2 \times 10^4$ mol.$^{-4}$ l.^{4} min.$^{-1}$

We interpret these results as showing that some stage of the reaction is subject to acid catalysis. In solutions containing primary or secondary amines and carbon dioxide, equilibria of the following type will exist:

$$\begin{array}{l}2R\text{NHMe} + \text{CO}_2 \overset{K_1}{\rightleftharpoons} R\text{NMeCO}\overset{-}{\text{O}}\,\overset{+}{\text{N}}\text{H}_2\text{Me}R \overset{K_2}{\rightleftharpoons} R\text{NMeCO}\overset{-}{\text{O}} + \overset{+}{\text{N}}\text{H}_2\text{Me}R \\ \qquad\qquad\qquad \updownarrow K_3 \hspace{16em} (1) \\ \qquad\qquad R\text{NMeCOOH} + \text{NHMe}R\end{array}$$

The species $\overset{+}{\text{N}}\text{H}_2\text{Me}R$ and RNMeCOOH might be expected to function as acid catalysts. Following Waley and Watson, we assume that the first step in the reaction is the reversible formation of a complex Y from the monomer M and the base X (reaction 2*a*). The complex may decompose with ultimate evolution of carbon dioxide by reaction with a further molecule of base (2*b*), or by different processes (2*c*) requiring the presence of acid catalysts.

$$\left.\begin{array}{ll} M + X \rightleftharpoons Y,\ K & (a) \\ Y + X \xrightarrow{k_1} (\text{carbamate salt}) \rightarrow 2X + \text{CO}_2 & (b) \\ Y + \left\{\begin{array}{l}X\text{H}^+ \quad \text{or} \\ \\ R\text{NMeCOOH}\end{array}\right. \underset{k_3}{\overset{k_2}{\rightarrow}} X + \text{CO}_2 + \left\{\begin{array}{l}X\text{H}^+ \quad \text{or} \\ \\ R\text{NMeCOOH}\end{array}\right. & (c)\end{array}\right\}(2)$$

The rate equation deduced from this scheme is

$$-\frac{\mathrm{d}[M]}{\mathrm{d}t} = K[M]\left\{\frac{(1+8K_1[\mathrm{CO}_2][X]_0)^{1/2}-1}{4K_1[\mathrm{CO}_2]}\right\}^2$$

$$\times\ \{k_1 + k_2\sqrt{K_1K_2}\,[\mathrm{CO}_2]^{1/2} + k_3K_1K_2\,[\mathrm{CO}_2]\},\quad (3)$$

where $[X]_0$ is the initiator concentration. In deriving this equation, it has been assumed that the equilibrium (2*a*) is effectively established throughout the reaction, and that $[Y]/[X]$ is small. The values of the rate calculated from (3) are shown as a function of the carbon dioxide concentration in the full curves in the diagram, using the numerical values of the various combinations of constants shown in the legend. The agreement with experiment is considered satisfactory.

Some support for the above mechanism is provided by the observation that addition of a weak acid—α-picolinic—in concentrations of about 10^{-3} molar (that is, of the order of 10 per cent of the initiating base) causes a marked increase in the rate of reaction. Further, in agreement with the postulated mechanism, the molecular weights of the polymer produced are independent of the concentration of added acid—whether α-picolinic or carbamic—although the rate of polymerization changes considerably.

We have found that the polymerizations of the N-carbonic anhydrides of DL-phenylalanine and DL-leucine in nitrobenzene solution are completely different kinetically from that of sarcosine. In these cases the reactions are first-order with respect to both monomer and initiator, and have positive temperature coefficients. Carbon dioxide shows no catalytic effect. It appears that with these anhydrides the rate-determining step is the forward reaction of (2*a*).

A fuller account of this work will be published elsewhere in due course.

Paper Electrophoresis of Sugars at High Potential Gradients

It has been shown by Consden and Stanier, Jaenicke, and others[1] that the application of electrophoresis on filter paper can give interesting results for the resolution of mixtures of certain sugars in borate buffers. Most workers used potentials of 200–300 V. and various systems of cooling, or no cooling at all. Although the separations of several hexoses and pentoses from one another and from some disaccharides and trisaccharides have been accomplished, the resolution of mixtures of disaccharides and higher oligosaccharides seemed to be more difficult and often not possible.

Foster[2] has reported the use of up to 1,200 V. or 24 V./cm. in the electrophoresis of carbohydrates, including some disaccharides, thus doubling the voltage of 10·3 V./cm. applied by Consden and Stanier. Michl[3] described the separation of mixtures of sugars, mainly hexoses and pentoses, applying a potential gradient of 44 V./cm. for 15 min. with an efficient cooling system at 10° C. While this work was in progress, the information of the use of very high potential gradients (50–120 V./cm.) by Kickhöfe and Westphal[4] for the separation of peptides cam to our knowledge rather belatedly.

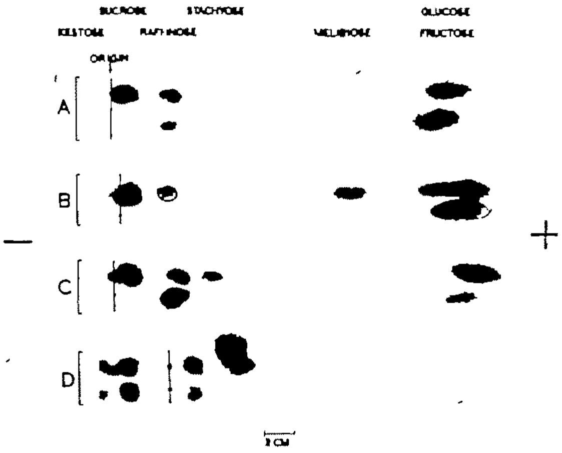

Fig. 1. Electrophoresis of sugars. (*A*) Sucrose, raffinose, fructose, (*B*) sucrose, raffinose, melibiose, glucose; (*C*) sucrose, raffinose, stachyose, fructose. Conditions: 40 V./cm., 8–12 m.amp., 1¼ in. × 22½ in. strip, Whatman No. 1, 0·05 *M* sodium borate solution, pH 9·2, 1·5 hr.; (*D*) kestose, sucrose, raffinose, stachyose; same conditions, but run for 3 hr. with origin line in centre of strip instead of 9 in. from cathode end; 5–20 μgm. of each sugar applied. Spraying reagent: α-naphthol and phosphoric acid; benzidine and acetic acid in (*B*)

Since the distance travelled within a given time i a function of, and directly proportional to, th applied potential, it was thought that a significan increase in the voltage and the use of a longer stri might make conditions more favourable for successf separations.

We have found in this laboratory that the application of high voltage is not difficult, once the proble of efficiently cooling the strip of paper has bee solved. The dissipation of the considerable amoun of heat generated had been first achieved by placin the strip between two sheets of ordinary windo glass which, in turn, are placed between two coppe plates cooled by tap water. This system has bee later improved on by substituting polythene o telcothene films (Telegraph Construction and Maintenance Co., Ltd., London) of 0·006 in. thickness fo the glass sheets. This ensures better cooling and easie handling of the apparatus, which will be describe in detail elsewhere. Strips of 1¼ in. × 22½ in. wer mainly used, allowing an effective length of abou 20 in. For some experiments, strips of 5 in. × 22½ in were found useful. Potential gradients of 40–60 V./cm have been applied for 1–3 hr. without difficultie Depending on the compounds involved, satisfactor separations can be obtained within 1 hr. Fig. demonstrates some of the separations.

The interesting point is that both raffinose an stachyose travel faster towards the anode tha sucrose, which is contrary to their behaviour on paper chromatogram. Glucose and fructose are no separated under these conditions, but can be resolve at a lower *p*H. Kestose, a new trisaccharide can be easily separated from raffinose, contrary t its chromatographic behaviour. Its separation fro sucrose is sufficiently clear provided their proportion are not too unfavourable.

It must be pointed out that the picture of th separations (Fig. 1) has suffered by the photosta method of copying adopted. The spots in *B* had to b ringed as the benzidine reagent did not give suitabl ntrast for copying. The high-voltage technique seems to offer a number of advantages, as present work this laboratory on the separation of incompletely verted sucrose has already shown. The high degree resolution and the great saving of time are only wo of them.

Thanks are due to Mr. H. C. S. de Whalley, director f research, for his interest in this work, and to the directors of Tate and Lyle, Ltd., for permission to publish this communication.

Analysis of Organic Hydroperoxides in the Presence of Hydrogen Peroxide

THE problem of identifying and estimating accurately organic hydroperoxides in the presence of hydrogen peroxide has recently been solved in these laboratories by two different techniques.

It has been found possible, by the use of filter paper chromatography, to resolve synthetic mixtures of hydrogen peroxide with such peroxides as methyl- or *t*-butyl hydroperoxides. The experiments were carried out with Whatman No. 1 papers placed, in the usual way, between two glass plates. Hydrogen peroxide and methyl peroxide were then separated by developing the chromatogram with ether, and showing the positions of the rings with a thiocyanate reagent. Hydrogen peroxide and *t*-butyl peroxide were conveniently separated with propyl alcohol, and the rings shown up with the usual reagents. The R_F values found were: in ether, hydrogen peroxide 0·4, methyl peroxide 1·0; in *iso*-propyl alcohol, hydrogen peroxide 0·74, *t*-butyl peroxide 1·0.

The first method is mainly qualitative, unless the chromatograms are compared with others obtained with standard mixtures of peroxides. The polarographic method has been applied to the quantitative estimation in two ways. One of these depends on the observation that in an alkaline medium (0·1 *M* lithium sulphate, 0·01 *M* lithium hydroxide), hydrogen peroxide gives two waves. There is first an anodic step with $E_{1/2} = -0·1$ V. (against a standard calomel electrode), and then the well-known, slowly rising cathodic step, with the approximate relation $E_{1/2} = -0·9$ V. The diffusion currents of hydrogen peroxide which correspond to these steps have equal and opposite values. The presence of organic hydroperoxides has been found to contribute only to the second, cathodic step, though with different diffusion currents (these results will be published in a later communication). It is thus possible to derive the total concentration (hydrogen + organic peroxides) from the cathodic step, and that of hydrogen peroxide only from the anodic step.

If the concentration of hydrogen peroxide is much greater than that of the organic peroxides, then the following modification is more suitable. The hydrogen peroxide is precipitated, in an alkaline medium of 0·2 *M* lithium sulphate and 0·05 *M* lithium hydroxide, by reaction with lanthanum acetate (0·01 *M*). An irreducible basic peroxide of lanthanum is formed, so that a polarogram now reveals only the presence of the organic peroxide. The hydrogen peroxide can then be liberated by acidifying the solution. The lower limit of detection is *c.* 10^{-5}–10^{-6} *M* peroxide.

The methods described are now being applied to the analysis of combustion products.

We wish to thank Sir Alfred Egerton for his guidance and encouragement in this work.

Kinetics of Porphyrin-catalysed Chemiluminescent Decomposition of Peroxides, and the Mechanism of Photosensitized Oxidation

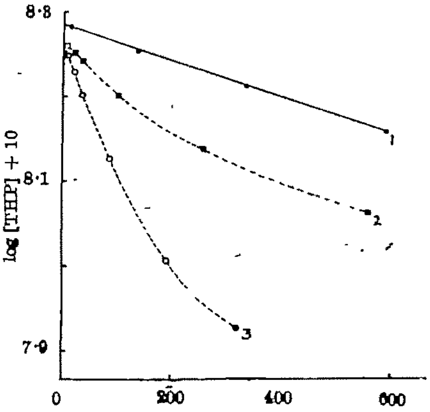
A RECIPROCAL relation between photochemical and chemiluminescent reactions is to be expected. In one case, absorbed light leads to chemical action, and in the other, chemical processes result in light emission. As part of a study of the mechanism of dye-sensitized photo-oxidations we have therefore investigated the kinetics of the chemiluminescent reaction between certain dyes and organic peroxides which was discovered by Helberger[1]. For example, magnesium phthalocyanine will catalyse the decomposition of tetralin hydroperoxide in hot hydrocarbon solvents, and this catalysis is accompanied by a bright chemiluminescence[1,2]. Zinc tetraphenylporphine and chlorophyll will also luminesce in these hot hydrocarbon–peroxide systems[2-4].

The reaction between zinc tetraphenylporphine[5] and tetralin hydroperoxide[6] was studied at 149° C. in *tert.*-butylbenzene solvent, chosen because of its high boiling point and low chain transfer constant[7]. All materials were carefully purified, solutions were rigorously de-oxygenated on the vacuum-line and reactions were run in sealed-off tubes. The dye was followed spectrophotometrically, the peroxide by a precise iodometric titration[8], and the emitted light measured by a photomultiplier photometer.

Typical results are given in the accompanying figure and table, showing respectively the catalytic effect of the porphyrin on the peroxide decomposition and data on the time course of the luminescence. The falling-off of the catalytic effect with time is

CHEMILUMINESCENT REACTION BETWEEN TETRALIN HYDROPEROXIDE AND ZINC TETRAPHENYLPORPHINE
Run, *L*-3; temperature, 149° C.; solvent, *t*.-butylbenzene

Tube No.	Time (min.)	[Tetralin hydroperoxide] × 10^{2} mol. $l.^{-1}$	[Zinc tetraphenylporphine] × 10^{5} mol. $l.^{-1}$	Light intensity ΔG (photometer reading)	k $\frac{[P][D]\times 10^{8}}{\Delta G}$
0	0	1·900	9·20	172	1·02
3	31·5	1·813	6·79	124	0·99
2	66·5	1·702	4·67	78	1·02
1	99·5	1·631	3·32	49	1·11



Catalytic effect of ZnTPP on decomposition of tetralin hydroperoxide: (1) pure THP; (2) [ZnTPP] = 8·08 × 10^{-6} *M*; (3) [ZnTPP] = 3·35 × 10^{-5} *M*. Solvent, *t*.-butyl benzene, temperature, 149° C.; $[THP]_0$ = 0·02 *M*

due to the gradual destruction of the dye. The essential results are as follows.

(1) At constant peroxide concentration the increase in the initial rate of peroxide decomposition above the uncatalysed unimolecular rate, caused by addition of dye, is proportional to the initial dye concentration.

(2) The initial rate of disappearance of dye is given by (D = dye, P = peroxide)

$$-\frac{d[D]}{dt} = k_D[D][P],$$

$k_D = 0{\cdot}5 \pm 0{\cdot}1$ l. mol.$^{-1}$ min.$^{-1}$, and, roughly, between 20 and 30 peroxide molecules are decomposed for each dye molecule consumed[4].

(3) The luminescence intensity is given quite accurately by

$$I = k_I[D][P].$$

(4) Cumene hydroperoxide and *tert*.-butyl hydroperoxide are very much less effective luminescent agents than tetralin hydroperoxide, in the reaction with zinc tetraphenylporphine. Di-*tert*.-butyl peroxide gives no visible emission at all.

In addition, from other work it is known that:

(5) α-Tetralone and water are the main products of the peroxide decomposition[6].

(6) In the case of chlorophyll, the chemiluminescence spectrum resembles the fluorescence spectrum of the original dye[9].

These facts are all consistent with the following mechanism for the peroxide–porphyrin reaction ($\overset{H}{>C}OOH$ = tetralin hydroperoxide; DH_2 = dye; DH_2^* = excited dye).

$$(A)\quad \overset{H}{>C}OOH + DH_2 \rightarrow \overset{H}{>C}O\cdot + DH\cdot + H_2O$$

$$(B)\quad \overset{H}{>C}O\cdot + DH\cdot \rightarrow DH_2^* + >C{=}O$$

$$(C)\quad DH_2^* \rightarrow DH_2 + h\nu.$$

Assuming reasonable values of the bond-strengths, the second step supplies enough energy to permit emission of a red photon. It is possible that the reaction proceeds generally without appreciable separation of the high-energy intermediates, which may be formed after initial complexing of the peroxide at the central metal atom. However, some side reactions must occur, as shown by the eventual disappearance of the dye. It is especially noteworthy that step (B) in the above mechanism is precisely the reverse of the initial step in a possible mechanism of photosensitization, in which the excited dye (or a long-lived excited product) is assumed to react with an acceptor to yield a pair of radicals[10,11]. Thus (A = oxidant, RH_2 = reductant):

$$(D)\quad DH_2^* + A \rightarrow DH\cdot + AH\cdot$$

$$(E)\quad DH\cdot + RH_2 \rightarrow DH_2 + RH\cdot$$

$$(F)\quad AH\cdot + RH\cdot \rightarrow AH_2 + R$$

Finally, we note that the complete reversal of the scheme of hydroperoxide decomposition leads to the splitting of water[12]. In the particular case studied here, it appears that there is insufficient energy in DH_2^* to run the process backward. However, one may conjecture that, in plant photosynthesis, water may be split between *two* radicals formed by hydrogen or electron transfer from the excited dye to a suitable acceptor.

Other mechanisms may be written, including those which do not assume removal of hydrogen from the catalyst. Thus, the initial step may be addition of peroxide across a double bond, with subsequent elimination of water, formation of ketone and regeneration of dye. However, this leads to some difficulty in understanding the mechanism of electronic excitation of the dye.

Further details of these and related experiments will appear shortly. This work is supported by grants from the Research Corporation of New York and the U.S. Atomic Energy Commission (Contract No. $AT(30\text{–}1)\text{–}820$). We are indebted to Prof. James Franck for helpful discussion.

5-Hydroxytryptamine in a Carcinoid Tumour

ERSPAMER[1] was the first to assume enterochromaffine cells of the gastrointestinal tract to contain enteramine (5-hydroxytryptamine serotonin). Feyrter[2] regarded these cells as a part of the entity he calls the "Helle-Zellen-Systeme" in general, subdividing it into the "Insuläres Gangorgan" of the pancreas, the probable origin of glucagon (Gaede, Ferner and Kastrup[3]), and the "Gelbe-Zellen" or enterochromaffine cells of the gastrointestinal tract. Carcinoids, which are tumours originating from these cells, have already been examined with regard to pharmaco-ynamically active substances by Feyrter and Unna[4] and by Selberg[5]. Their results were inconclusive and ivergent.

A carcinoid found at post-mortem has been extracted with $N/50$ hydrochloric acid. This extract, dministered in amounts corresponding to as little s 5 μgm. tumour (fresh weight) on an isolated rat's terus (2-ml. bath), showed remarkable activity. Detailed pharmacological analysis (rat's uterus and olon; guinea pig's and rabbit's ileum; desensibilization by large doses of 5-hydroxytryptamine; blood pressure; innervated and denervated nictitating membranes; perfusion of rabbit's ear; paper chromatography with 70 per cent *iso*propanol : 30 per cent $N/10$ hydrochloric acid; and diazo and quantitative colorimetric estimations) revealed the presence of at east 2·5 mgm. 5-hydroxytryptamine per gm. tumour (fresh weight). A second substance, also active on the gut, but not inhibited by a large dose of 5-hydroxytryptamine, which did not give a diazo reaction and had a lower R_F value, could be distinguished from 5-hydroxytryptamine. It seems to be responsible for about half the activity on the guinea pig's ileum. Acetylcholine, histamine, adrenaline and substance *P* could be excluded.

These findings are in complete corroboration with Erspamer's assumption on the origin of 5-hydroxytryptamine. Furthermore, they can be regarded as a support for Feyrter's views on the functional unity and the significance of the enterochromaffine cells as an endocrine organ.

Rates of Glycolysis in Human Red Cells in Relation to Energy Requirements for Cation Transport

The extrusion of sodium and accompanying potassium accumulation by red cells against electrochemical gradients is linked to the energy of cell glycolysis[1,2]. Active cation transport ceases at low temperatures, in the presence of iodoacetate or fluoride, and in the absence of glucose. *Per contra*, the process is unrelated to red-cell respiration, since transport is not influenced by cyanide, azide, carbon monoxide, methylene blue, pyruvate or malonate.

Solomon[2] has discussed the energetics of sodium–potassium transfer across the human red-cell membrane. In fresh blood incubated at 37° C., the rate of disappearance of glucose was 2·33 m*M*./l. red cells/hr. Using the value of 48,000 cal./mol. for the anaerobic metabolism of glucose, the energy released was 110 cal. Evaluation of the exchange of sodium-24 and potassium-42 indicated that maintenance of the cation steady state could utilize a *maximum* of 8 per cent of the total energy released by red-cell glycolysis. Raker *et al.*[3] reported a glucose utilization of 1·4 m*M*./l. red cells/hr. for comparable systems and rates of cation transport. In blood incubated with glucose at 37° C. after cold-storage for 2–7 days, the glucose utilization ranged from 1 to 1·5 m*M*./l. red cells/hr.[1,4].

While in the latter experiments it may be assumed that the leucocytes are either absent or non-viable, the former investigators have apparently not assessed the glycolytic activity of white cells. Hsu[5] found dogs' white cells to have about a thousand times the glycolytic activity of red cells. The relative effect of human red and white cells on blood glycolysis has been studied during an investigation on cation transport (to be published).

Fresh heparinized blood from young healthy adults was divided into two unequal portions, the smaller being kept at room temperature. The larger sample was spun, the plasma removed and retained. The buffy coat and upper red-cell layer were aspirated and discarded. The packed red cells were suspended in an equal volume of original plasma (one tube refrigerated at 4–8° C.) and of buffer (sodium chloride, sodium bicarbonate, glucose at *p*H 7·8); counts on such suspensions showed less than 100 white cells per c.mm.

The samples (whole blood, red cells in plasma and in buffer) were incubated at 37° C. for 3 hr. after equilibration with 5 per cent carbon dioxide. Eighteen specimens utilized glucose at rates of 1·2–2·2 m*M*./l. formed elements/hr., compared with 0·9–1·35 (mean, 1·18) m*M*./l. red cells/hr. for red cells suspended in their own plasma and 5–10 per cent less in the buffer medium. Standardized to a hypothetical blood containing 5×10^6 red cells and 5×10^3 white cells per c.mm., the white cells are responsible for about 25 per cent of the total glucose utilization.

Lactic acid formed in the whole blood samples corresponded to 70–90 per cent of the glucose which disappeared. For the red-cell suspensions it was 91–98 per cent; such quantitative conversion is supported by other workers[1,3]. The slight respiration of red cells (Q_{O_2}, 0·05) appears to be related to the oxidation of glucose-6-phosphate through phosphogluconic acid to triosephosphate rather than the citric acid cycle[6].

Glycolysis exhibits progressive inhibition above and below *p*H 7·0–7·8. However, *p*H values after 3 hr. incubation did not decrease more than *p*H 0·2 from initial levels of *p*H 7·2–7·4 and 7·6–7·8 for the plasma and buffer suspensions. Longer incubation accelerated the change.

The energy of glycolysis is 36,000 cal./mol. glucose; of this, the free energy capture is represented by the net gain of two high-energy phosphate bonds of adenosine triphosphate, that is, 23,000–24,000 cal./mol. glucose[6,7]. Hence the utilizable free energy is some 28 cal./l. red cells/hr.

The plasma and red cell sodium and potassium values did not alter more than 0·5 meq./l. during incubation. The maximum free energy required for sodium and potassium transport in the steady state is 1,510 and 2,350 cal./mol. (calculated from the formulation of Ussing[8] and assuming that the cations are freely exchangeable). In the steady state, the outward movement of sodium-24 is 3·08 meq./l. red cells/hr. [2], and the inward flux of potassium-42 is 1·5–1·7 meq./l. red cells/hr. [2,9]. Transport of these ions thus requires a maximum of 4·65 and 3·8 cal./l. red cells/hr. Cation balance of red cells may, therefore, utilize up to a third of the available free energy from glycolysis.

The red cell suspensions, refrigerated at 4–8° C. for 1–3 days, showed decreases of red-cell potassium of 5–20 meq./L., with somewhat greater sodium increases. When incubated with glucose at 37° C. for 3 hr., the energy calculated to restore normal cell cation relations did not exceed the available free energy.

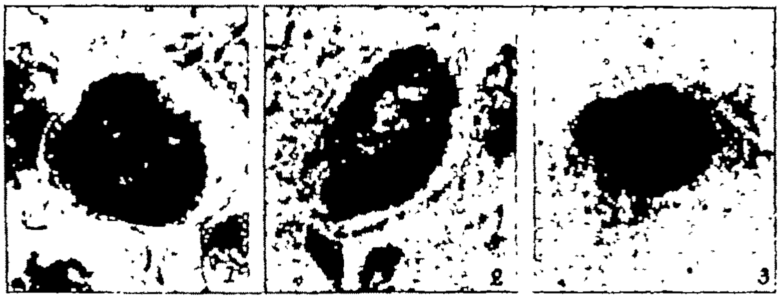
Protective Activity of Cysteinamin against the Toxicity of Dihydrostreptomycin

IT has been demonstrated by L. E. Floberg, C. A. Hamberger and H. Hyden[1] that the cells of the ganglion of Scarpa in guinea pigs, intoxicated with streptomycin, showed a definitive decrease of ribonucleic acid content.

We have performed experiments which show a diminution of ribonucleic acid in the cells of the ganglion of Scarpa in rabbits intoxicated with dihydrostreptomycin. In a normal rabbit the protoneurons of that ganglion present a very variable charge of basophilic substances (as demonstrated by Brachet's method). Three schematic types have been distinguished, according to the decreasing contents of ribonucleic acid. Most of them display a very large number of Nissl's bodies (Type I, Fig. 1). In others those bodies form only a perinuclear or peripheral layer (Type II, Fig. 2). Others still are practically empty of them (Type III, Fig. 3).

It appeared that, in the ganglions of fifteen rabbits intoxicated with dihydrostreptomycin up to loss of the labyrinthic reflexibility, the number of protoneurons poorer in basophilic substances was more important than in fifteen controls of the same age. This was confirmed by counting a sufficient number of cells and by distributing them into three groups corresponding to the three different classes according to the classification mentioned (see table).



Figs. 1–3. The three schematic types of ganglionary cells defined in the text. (1) A cell full of Nissl's bodies; (2) a cell with only a peripheral layer of Nissl's bodies; (3) a cell with no Nissl's bodies

	Type I (per cent)	Type II (per cent)	Type III (per cent)
Controls	55 42	35 48	10 10
After Dihydrostreptomycin	14 10	47 48	39 42
After cysteinamin Dihydrostreptomycin	58 32	40 60	2 8

We have already shown[2] that the toxic effect of dihydrostreptomycin can be eliminated by preliminary injections of cysteinamin (for details about the experimental conditions, see ref. 2). In those cases the vestibular reflexes remain normal and the microscopic examination of the ganglion of Scarpa from the fifteen rabbits protected by cysteinamin reveals an aspect similar to that of a normal ganglion of Scarpa.

The table indicates the percentage of the three above-mentioned types of cells after classification of 250 cells from two controls, two animals intoxicated by dihydrostreptomycin and two animals previously protected by cysteinamin.

Moreover, it has been observed that dihydrostreptomycin precipitates ribonucleic acid *in vitro*, possibly by formation of an insoluble complex. A concentration of 250 γ or more of dihydrostreptomycin with a constant quantity of ribonucleic acid (2,000 γ per c.c.) induces a precipitation which does not appear for the same concentration of ribonucleic acid when more than 200 γ cysteinamin is added. The mechanism of this process and its possible relation with our biological observations, however, will be further investigated.

Turbidity-reducing Activity of Influenza Virus and Receptor-destroying Enzyme on Sheep Submandibular Mucoid

A CHARACTERISTIC turbidity develops when polymerized hyaluronic acid is mixed with acidified horse serum; this turbidity, and its destruction by prior incubation with hyaluronidase, is the basis of the turbidity-reducing test for the enzyme[1]. Solutions of highly purified mucoprotein from the salivary glands of sheep[2] also develop turbidity when treated under suitable conditions with acidified horse serum. Moreover, development of turbidity is significantly reduced by previous incubation of the mucoprotein with certain strains of influenza virus, or with the receptor-destroying enzyme of *V. cholerae*. In this preliminary communication we show that the turbidity-destroying activity of influenza virus is associated with the virus particles themselves, and is presumably a function of the enzymatic properties of the virus[3].

Mucoprotein solutions used included several partially purified preparations and one, homogeneous

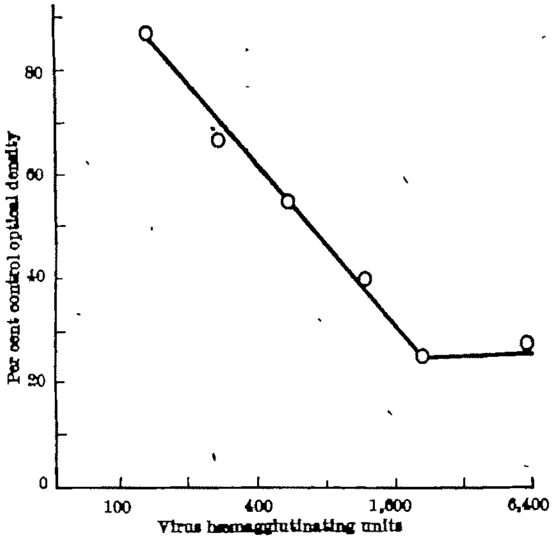

Fig. 1. Turbidity reduction by concentrated *WS* influenza virus on homogeneous sheep salivary mucoprotein

on electrophoresis and ultracentrifugation, which inhibited agglutination[4] by indicator *LEE* influenza virus at a concentration of 0·001 μgm./ml. All preparations became turbid when mixed with acidified horse serum, the purest preparations giving rise to the highest turbidity per unit weight. For turbidity-reducing assay, the concentration of mucoprotein was adjusted to give an optical density of 0·20–0·25 unit on the colorimeter.

The method of assay was essentially similar to that used for the turbidimetric assay of hyaluronidase: 0·1 ml. of mucoprotein (4–8 mgm./ml. in distilled water, depending on the purity of the sample used) was distributed in small tubes, and 0·1 ml. of saline buffered at *p*H 5·4 with 0·2 *M* acetate buffer containing 0·1 per cent calcium chloride was added to each tube. Serial dilutions of virus or enzyme (0·1 ml.) in buffered saline were then added, and the tubes incubated in a water-bath at 37° for 1¼ hr. Control tubes with heat-inactivated (56° for 15 min.) virus or enzyme were included in each assay. On removal from the bath, 4 ml. of 0·5 *M* acetate buffer *p*H 3·8 was added to each tube, followed by 1 ml. of horse serum diluted 1 : 5 in acetate buffer and adjusted to *p*H 3·8. After mixing, the turbidities were developed for 30 min. at room temperature and read against a blank solution of buffer and horse serum in a Coleman spectrophotometer at 450 mμ.

The effect of incubating mucoprotein with falling amounts of influenza *A* virus, strain *WS*, purified by high-speed centrifugation, is shown in Fig. 1. A significant reduction in turbidity occurred after exposure to virus. Over a certain range (approximately 200–2,000 hæmagglutinating units) the reduction was directly proportional to virus concentration. At more than 2,000 hæmagglutinating units, however, turbidity was not further reduced with increased virus concentration; this residual turbidity varied between 5 and 30 per cent of the original turbidity, depending on the purity of the mucoid sample. No significant reduction in turbidity occurred after incubation with normal allantoic fluid or heat-inactivated virus.

The optimum reaction for destruction of turbidity was between *p*H 5·4 and 5·8. The destruction was stimulated by calcium ions and partly, though not entirely, suppressed by anti-calcium agents and specific antiserum. Reduction of turbidity by purified virus was 75 per cent complete after incubation for 30 min. and 85 per cent complete after 1 hr. It was shown most consistently by strain *WS*, either as high-titre allantoic fluid, or when deposited at 20,000 *g* and resuspended in Ringer's solution. Strain *Melbourne* was approximately twice as active as *WS* per hæmagglutinating unit; but with this strain only approximately one in three high-titre crude allantoic fluids showed the effect. Reduction of turbidity by *Melbourne* virus could, however, be consistently demonstrated with pooled virus passed at limiting dilution and deposited by high-speed centrifugation. Virus (*WS* or *MEL*) was more active per hæmagglutinating unit after centrifugation and resuspension in Ringer's solution than in the original allantoic fluid. The turbidity-reducing agent of resuspended virus was also considerably more stable than that of virus in allantoic fluid, which showed a marked drop in activity after 24–48 hr. at 4°. No turbidity-reducing activity has so far been demonstrated by concentrated *neuro-WS*, or by *PR*8, *A′*, *NDV*, *LEE B*, and mumps viruses in high-titre allantoic or amniotic fluids.

A marked and rapid drop in turbidity occurred when salivary mucoprotein was incubated with purified *V. choleræ* receptor enzyme[5] under the above conditions. Heated enzyme was entirely without effect. As little as 1 μgm. of pure enzyme produced a significant drop in turbidity: studies of the kinetics of the reaction indicated that it was complete in 30 min. and typically enzymatic.

The purified virus inhibitor from human urine[6] also developed turbidity with acidified horse serum, and this turbidity was reduced by at least 50 per cent after exposure to virus or receptor enzyme. None of the receptor-substance mucoproteins isolated from human erythrocytes[7], however, developed turbidity under the same conditions.

From the above results it may be concluded that allantoic fluid infected with certain strains of influenza *A* virus contains a factor which reduces the turbidity produced by mixing purified mucoprotein virus inhibitors with acidified horse serum. It is probable that the turbidity-destroying factor is associated with the virus particles themselves, since the effect is best shown by virus purified by high-speed centrifugation, or by adsorption to, and elution from, erythrocytes. No activity is shown by normal allantoic fluid, by infected fluids with hæmagglutination titre of less than 500, or by allantoic fluid from which virus has been deposited by centrifugation. Further, it is likely that turbidity-destroying activity is a function of the viral receptor-destroying enzyme, as may be seen from its thermolability, sharp *p*H optimum, and, most significantly, by its duplication in all respects by purified receptor-destroying enzyme of *V. choleræ*.

A purely physico-chemical method for the estimation of the receptor enzymes of influenza virus and *V. choleræ* offers obvious advantages over previous methods[8] dependent on red-cell agglutination, which give subjective and comparatively inaccurate end-points. With the present method one may define the activity of receptor-destroying enzyme precisely in turbidity-reducing units per unit weight, as is done with hyaluronidase, and the same holds for purified virus. The accuracy and reproducibility of the method make it particularly suitable for physical studies of viral and bacterial receptor enzymes to be described elsewhere[9].

The turbidity-reducing phenomenon also throws light on the nature of the interaction between viral enzymes and their mucoprotein substrates. Gottschalk and his collaborators[10] have shown that an N-substituted fructosamine (*iso*glucosamine) is liberated as an end-product of the interaction between influenza virus and partly purified mucoprotein substrates. The turbidity-reducing action of *MEL* and *WS* viruses suggests that, as with hyaluronidase, the initial attack on the substrate is a depolymerization which precedes the liberation of substances reacting with Ehrlich's reagent. Finally, the turbidity-reducing reaction provides truly *in vitro* evidence of the reality of enzymic action by influenza virus.

Hæmagglutinin Anti-*N* in Plant Seeds

SOME plant seeds contain specific antibodies for the antigens *A*, *B* and *O* (or *H*) of human blood[1,2]. *Rh*, *M* and *N* antibodies have been sought, but with negative results[3]. Through the courtesy of Prof. K. Mohrdiek (Porto Alegre), we received seeds of four species of *Vicia* from southern Brazil. Seed extracts were made and tested in the usual manner[1], except that the blood cells were washed once and readings made with a hand lens. The seeds of one species were found to contain anti-*N*.

The freshly prepared extract of *Vicia graminea* agglutinated *N* or *MN* cells, the titre being 32 to 64 after one hour at 4°, 20° or 37° C. The extract diluted 1 : 4 left as a rule suspensions of *N* cells unaltered after one hour, although some *M* samples did react. The same dilution of the extract agglutinated after half an hour, of a total of twenty-five samples, all the twelve *N*-positive and none of the thirteen *N*-negative ones. This would demonstrate that the antibody of the extract is anti-*N* if we were dealing with an independent antigen – antibody system. Generally, however, *N* occurs more often with *s* than with *S*. To exclude anti-*s* we made use of anti-*S*, since we had no anti-*s*; and some *S*-negative, hence *s*-positive, samples gave negative reactions with the extract 1 : 4 after half an hour. Under the same conditions eighty-three random blood samples were examined, fifty-seven of which gave positive and twenty-six (or 31 per cent) negative reactions with the extract, in agreement with the frequency (30·6 per cent) of type *M* in São Paulo[3,4]. Among those eighty-three reactions only one was doubtful, and the respective sample was shown to be *MN* with unusually weak *N*. In conclusion, the extract of *Vicia graminea* contains *N* antibody of an activity and specificity not much inferior to those of the animal anti-*N* sera in use.

As to the other seeds, the extract of *Vicia linearifolia* failed to agglutinate human blood even after three hours. In the seeds of *Vicia sativa* and *Vicia benghalensis* strong agglutinins were present but without distinct specificity for *A*, *B*, *O*, *M*, *N*, *S*, *P*, *C*, *D*, *E*, *c*, *d*, *e*, *Lu*, Le^a, *K* or Fy^a.

Yet, since one among four species of *Vicia* displayed specific hæmagglutinin not related to the *ABO* system, it seems probable that the screening of such extracts with a large panel of blood cells might lead to the discovery of more specimens of *N* antibody and even of hæmagglutinins of other specificity.

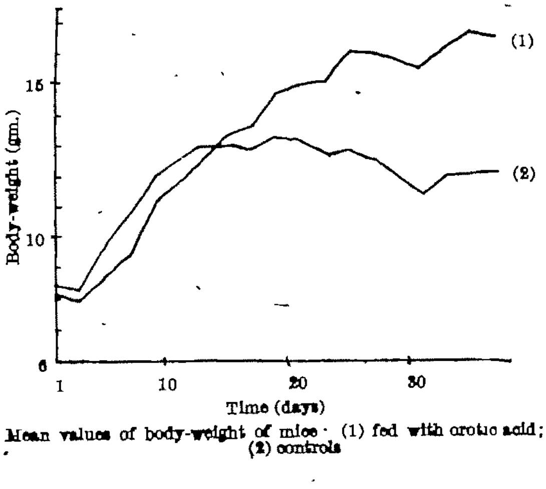
Orotic Acid as One of the Growth-factors of Mice

IN 1946 it was shown in our laboratory[1] that orotic acid causes an increase in the reticulocytes in circulating blood, but its action in increasing the body-weight of albino rats by administering orotic acid to animals fed on a basic diet was not made clear. This was attributed to the fact that the basic ration was inadequate. Three years ago we conducted feeding experiments, again with mice instead of rats, and confirmed the growth-promoting action of this acid. This time the experiment was conducted as follows. The basic ration was composed of rice starch 0·6 gm., casein 0·2 gm., lard 0·15 gm., McCollum salt 0·05 gm. Moreover, each animal was given 0·1 gm. of yeast dry powder and two drops of cod liver oil daily. Rice starch was prepared from the polished rice, which was further freed from its embryos by means of hand. Seven litters weighing 7–7·5 gm. born of the same dam were used. Four of them were fed with 5 mgm. of orotic acid daily besides the basic diet; the remaining three were kept on the basic diet only as controls. Until the eleventh day from the beginning of the



Mean values of body-weight of mice: (1) fed with orotic acid; (2) controls feeding experiment, no difference between the experimental group and control appeared; but after that increase of body-weight in the latter group ceased or became slowed down considerably, thus contrasting remarkably with that of the experimental group the body-weights of which increased considerably (see accompanying graph).

As cow's milk contains a considerable amount of orotic acid, it is possible that the remarkable increase of body-weight in the calf may be attributed partially to the existence of this acid in cow's milk. (Formerly it was suggested[1] that orotic acid may have some promoting action upon the lactation of certain animals.)

From the above result, orotic acid might be reckoned among growth-factors essential for mice, and presumably also for other animals.

Experimental Production of Hepatic Necrosis and Fibrosis with Water

IN the course of experiments devised to study the effects of the parenteral administration of various types of fluids on lymph-flow in the rat, I had occasion to introduce sterile distilled water intravenously by way of the portal vein. As a result of this procedure, observations were made on the production of acute hepatic injury followed by fibrosis.

Normal adult male rats of the Long–Evans strain, unfasted, were anæsthetized with ether. Through a 3-cm. ventral midline abdominal incision, and using appropriate retraction, the duodenum was displaced caudally in such a manner as to expose the portal vein. Using a No. 27 hypodermic needle, 20 ml. (about 5 per cent of the body-weight) of sterile distilled water prepared for parenteral use was injected over a 5–10 min. period. The rate of injection was carefully regulated to prevent undue distension of the portal vein or the production of back pressure in the portal tract. The site of injection was generally at the junction of the splenic and superior mesenteric vein. Since the vein is quite thin, care must be exercised in the technique of injection, else severe hæmorrhage will ensue, in the event of slight tearing or undue distension of the vein. The incision was repaired, and the animals were allowed access to food and water. For study of liver tissue, biopsy specimens were taken before injection, 5–10 minutes after injection, and at intervals of 1–2 weeks. Tissues were fixed in Bouin's or 10 per cent formalin. Frozen sections were stained with sudan IV and hæmatoxylin; other sections prepared by the nitrocellulose technique were stained with hæmatoxylin and eosin. Appropriate controls were studied, using equal amounts of 0·9 per cent sodium chloride solution. All solutions were injected at room temperature.

The slow injection of water into the portal vein as described above produced a generalized mild blanching of the liver after the introduction of 2–4 ml. of fluid. This blanching was maintained for the period of injection, scattered lobular areas becoming more markedly pale. On cessation of the injection, the liver slowly regained its normal colour, save for the scattered pale areas noted during injection. Blanching and subsequent injury did not occur after similar portal injection of 0·9 per cent sodium chloride solution, or after injections of water were introduced into a systemic vein (external jugular).

Study of the changes occurring in the liver within 10 min. after portal vein injection were made on sudan-stained frozen sections. Comparison of the pre-injection biopsy specimen with the injected specimen revealed increases in histologically visible parenchymal, finely granular fat with some evidence of scattered lipid vacuole formation. The most prominent changes, however, were noted in the immediate widespread evidence of centro-lobular non-lipid cellular vacuolation, with evidence of parenchymal swelling. Upon autopsy after an interval of 3–5 days, irregular and variable gross scarring of the liver surface was noted. Sections of the involved areas revealed areas of complete parenchymal necrosis. Scattered in these areas of necrosis and fibrosis, and in relationship to the portal triad, were noted areas of active regeneration, evidence of hepato-cellular loading with fine and globular fat in these cells being marked. Certain of the degenerative areas exhibited evidence of anæmic infarction, and some hæmorrhagic areas were noted, but no gross thrombi were seen. Repetition of the injection of water into the portal vein of individual animals after intervals of 4–6 weeks produced a more marked and diffuse type of gross scarring. Animals treated in the manner described did not exhibit gross evidence of jaundice. No convulsions or evidence of water intoxication were noted. Hæmoglobinuria was evident for the first few days.

The list of agents known to cause experimental and clinical hepatic injury is long. The nature or mode of action of these agents has been extensively studied in the experimental and clinical laboratory. The pathogenesis involved has been summarized and described by various authors[1-3]. The present experiments add water to this list of hepatotoxic agents as a necrotizing and cirrhogenic agent. The similarity of the lesions produced by water to those produced by other necrotizing chemical agents suggests, however, that alteration of cellular permeability to water may be a common property of many of these agents[3].

Of importance is the implication from the present experiments that alterations in osmotic and electrolyte equilibrium may be an immediate factor in the causation of hepatocellular injury. In 1935, Selye, Collip and Thomson[4] demonstrated that the systemic intravenous administration of isotonic saline solution would, under certain conditions, produce fatty liver and ascites in the rat, and Møller-Christensen[5] has recently summarized his own and previous evidence showing liver injury occurring in the production of an eclampsia-like symptom-complex, produced in the rat by oral administration of water and injection of vasopressin. Generally, however, but meagre attention has been paid to the potential role of water and electrolyte disturbances in the production of liver damage and disease. Although no immediate parallel to the present experiment is found under natural conditions (cf. intravenous injection of fluids in the anæsthetized state), it must, however, be suggested that alterations in absorption of water and/or electrolytes may be of great importance in eliciting hepatic parenchymal damage and that attention must be paid to the role of various components of the diet, that is, protein, fat, carbohydrate, various lipotropic substances, vitamins and electrolytes, in altering water absorption. The implication, of course, is that the products of gastro-intestinal absorption may be altered in such a way as to present an abnormal circulating medium to the liver cells.

The present experiments provide a rapid method for the production of liver damage which may be of value in the evaluation of the relative significance of various dietary components, lipotropic, carcinogenic, cirrhogenic and hormonal agents, as related to the prevention and treatment of liver injury.

Reducing Substances in *Zostera*

DURING a study of the reduction of sulphates in *Zostera* mud flats, it was found that when autoclaved *Zostera* was added to autoclaved sand and sea water, ferrous sulphide was rapidly produced. At first it was thought that this reduction was microbiological, but later it was found that living *Zostera* could bring about the reduction. A study of *Zostera* showed that a lead mirror could be produced from lead acetate by heating this substance with *Zostera* leaves and that this mirror was intracellular in the leaf parenchyma. When washed *Zostera* leaves are heated with distilled water, cadmium acetate papers show yellow cadmium sulphide, and, at times, metallic cadmium. If the distillation is carried out under nitrogen, the steam distillate condensed into 100 ml. of $N/1,000$ hydrochloric acid at pH 3·35 yields a nitrogenous solution containing up to 6·75 mgm. nitrogen per litre, and the pH rises to 7·0 with a volume increase to 450 ml. In addition, there is a volatile sulphur-containing substance which is soluble in alcohol and produces lead sulphide from lead acetate. This sulphur compound gives no precipitate with mercuric chloride and a white precipitate with alcoholic lead acetate, suggesting a thioether. It has an unpleasant odour. The production of lead sulphide from lead acetate seems to depend on a partial volatilization of the nitrogenous base. *Posidonia* appears to contain a different sulphur derivative with a more pungent odour.

Both these substances are present in small amounts and their relative proportions in the plant seem to vary considerably. During October–November, little of the sulphur compound was present in *Zostera*; but after flowering in January, the sulphur compound increased while the nitrogenous base disappeared. The latter was still present, however, in *Zostera* from a bed that was not flowering. These substances are possibly united in the plant with a redox pigment, probably of a depside glucoside nature.

The existence of these two substances may be of great importance in *Zostera* muds in two ways: they may produce ferrous sulphide directly, and may also bring about reducing conditions that greatly accelerate sulphate reduction by *Microspira*.

Action of Insecticides on a Stem Borer of Oats: the Frit Fly

IN an attempt to assess the possibility of controlling gramineaceous stem borers by systemic and seed-dressing insecticides, the following results were obtained in laboratory and field experiments with larvæ of flies of the 'frit' complex, *Oscinella frit*.

Initial tests of the toxicity of 'Pestox 14' or *bis* dimethylamino-fluorophosphine oxide (Pest Control, Ltd.) to larvæ immersed in aqueous solutions of different strengths showed 71 per cent mortality with 0·0005 per cent and 100 per cent with 0·005 per cent after three days. There was apparently no difference in toxicity to different instars.

PERCENTAGE MORTALITY TO MIXED INSTAR LARVÆ OF SOLUTIONS OF 'PESTOX 14'

Strength of solution (per cent)	Time of immersion		
	6 hr. (per cent)	24 hr. (per cent)	3 days (per cent)
0·0005	0	14	71
0·005	0	100	100
0·05	59	100	100
0·5	100	100	100
Water	0	0	0

'Pestox 14' caused shrivelling of the larvæ proportional to the concentration and probably due to osmotic dehydration. This effect differs from the turgidity observed in death from parathion.

That translocation of systemic insecticides can occur in members of the Gramineæ is supported by work on the wheat bulb fly (*Hylemyia coarctata*) by Pest Control, Ltd., by the Overseas Food Corporation on sorghum central shoot borer (*Atherigona indica fuscata*), by Questell and Conin[1] on the toxicity of maize tissue to European corn borer (*Pyrausta nubilalis*), and by death of aphids on young oats grown in pots and watered with 0·05 per cent 'Pestox 3' (octamethylpyrophosphoramide or 'Schradan') after twenty-four hours during the present experiments.

Individual oat seedlings grown in Pfeffer's solution and infected with larvæ in the laboratory were used to demonstrate that 0·1 per cent 'Pestox 3' and 0·1 per cent 'Pestox 14' killed all larval stages in the stems in two to three days after the insecticides were introduced into the culture solutions. With potted seedlings grown in soil, however, watered with 'Pestox 3' at rates to give 50, 180 and 300 parts per million of soil, no dead larvæ could be found and progressively fewer live larvæ remained in the plants down to none at the 180 p.p.m. level, suggesting a specific repellant action on the larvæ.

In the field, counts of infested tillers in plots of 3 sq. ft. showed that, at a rate equivalent to 200 gallons per acre, 'Pestox 3' at 0·5 per cent killed 36 per cent, and at 1 per cent killed 75 per cent of the larvæ present, while 'Pestox 14' and parathion, both at 0·5 per cent, killed 20 per cent and 100 per cent respectively at 4 days after spraying. None of these treatments was phytotoxic at these concentrations although 'Pestox 3' has since been found to be the least phytotoxic. It is of interest that Schrader[2] found parathion to be effective against *Chortophila* and *Contarinia* at 0·01 per cent.

There was evidence of superior growth after treatment with 0·1 per cent 'Pestox 14' and 0·5 per cent parathion, observed by Chao-Seng Tsi[3]; but subsequent equalization takes place and final yields were not statistically different.

Seed dressing with gamma benzene hexachloride dressings ('Mergamma *A*', Plant Protection, Ltd.) at the recommended rate of 2 oz./bushel reduced the dead-heart rate from 61 to 48 per cent and also markedly stimulated growth. Heavier doses of benzene hexachloride soil-type insecticides as seed dressings and soil dressings also reduced frit attack but tended to be phytotoxic at the levels used.

Preliminary experiments of soaking seeds in systemic insecticides, reported to be effective with beans by Chao-Seng Tsi[3], indicated that soaking in 0·5 per cent 'Pestox 3' was not phytotoxic and that 17 hr. was the most effective time for absorption.

The above was part of a thesis submitted while studying under a Colonial Insecticide Studentship at the Imperial College Field Station, Silwood Park, Ascot, Berkshire. Acknowledgment is due to Dr. W. F. Jepson and other members of the staff for help and advice.

Boiling Point of Capillary-condensed Water

A CONSIDERABLE amount of experimental work on freezing-point depressions of capillary condensates has been reported in the literature in recent years[1]. Carman[2] has given an account of a few more properties n which capillary-held liquids differ from the same materials in bulk conditions. Boiling points of condensates, however, do not appear to have been studied in detail. We have devised a simple method for this purpose. The apparatus, in its essentials, onsists of a small vessel, which contains the capillary ystem under examination; it is connected to a vacuum pump as well as to a suitable differential manometer and is placed in an oil-bath, the temperature of which an be gradually raised. The vessel is first evacuated, and the manometer then registers the vapour pressure f the liquid under examination. The temperature f the bath is then gradually raised until the vapour pressure becomes equal to the atmospheric pressure. The temperature recorded then is the required boiling point.

Boiling points of water held at different vapour pressures in four different porous bodies (silica gel, sugar, charcoal, a sample of bentonite and a sample of clay loam), varying largely in their pore size-distribution relationships, were determined by means of this technique. The results showed that, for a given capillary radius, boiling-point elevation is about the same, irrespective of the nature of the adsorbent or the amount of the liquid contained in it.

The boiling-point elevations of water (average values for the four adsorbents) condensed in pores of radii less than 1060, 102, 30, 15·5 and 9 A. were found to be 2·4°, 4·9°, 12·6°, 21·2° and 34·1° C. respectively. These values agree well with the theoretical values calculated from thermodynamic considerations based on the theory of capillary condensation.

A detailed account of this work will be published elsewhere.

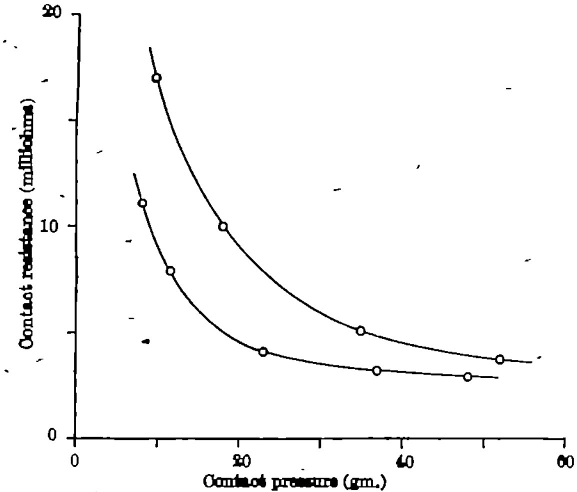
Electrical Contact Resistance between Magnetically Attracted Bodies

IN the course of work upon the characteristics of light-current contacts, the electrical resistance between contact-making members of magnetic material drawn together magnetically has been compared with that between the same members pressed together by an external force.

In both cases individual measurements for the same contacts at the same mechanical pressure vary considerably; but in all the experiments so far completed the average contact resistance over a large number of trials has been less—sometimes substantially less—when the pressure has been applied magnetically.

The accompanying curves show the variation in contact resistance with contact pressure for a contact comprising a nickel block and the tip of a thin nickel-plated steel strip. In the upper curve the pressure was applied gravitationally after demagnetization of the specimens, and in the lower (apart from about 1 gm. due to the weight of the steel strip) by magnetic attraction. In both cases the pressure was measured by means of a counterweight arranged to separate the contact members. The gross contact area was approximately 20 mm.² and the current (constant) was 0·1 amp. The tests were carried out under ordinary room conditions.

Each point on the curves represents the arithmetical mean of eighty measurements. Between each measurement and the next, the tip of the steel strip was given a slight lateral displacement by sliding it on the nickel block. The current was cut off during this operation; but the contact pressure was maintained. Magnetic and gravitational measurements were made alternately in sets of ten at each contact pressure. Half



the measurements were made with ascending, and half with descending, values of pressure.

The standard errors of the means were as follows, taking the points in order from left to right along each curve:

Gravitational points	0·84	0·70	0·25	0·28		$\Omega \times 10^{-3}$
Magnetic points	0·53	0·36	0·12	0 09	0·15	$\Omega \times 10^{-3}$

More than one factor may contribute to the effect noticed. Apart from any resistance due to surface film, the spreading resistance from an ideal contact spot on a comparatively large contact member is inversely proportional to the radius of the spot[1]. The pressure necessary to produce a spot, on the other hand, increases more rapidly than the radius. Its value depends upon whether the deformation is predominantly elastic or predominantly plastic[2]; but in general it is proportional to at least the square of the radius. Under these conditions, any increase in the number of contact spots for a given total pressure will result in a decrease in the joint resistance of the several spreading resistances in parallel.

Contact members drawn together magnetically seem likely to have more contact spots, and hence a lower contact resistance, than the same members pressed together blindly by an external force, since in the magnetic case an increase in the force will tend to form new spots by drawing together points almost but not quite touching, rather than merely to increase the size of existing spots. Magnetic saturation will no doubt occur at established spots; but this will promote rather than hinder the formation of new spots elsewhere.

Again, an external force may be partly wasted upon particles of insulating (and therefore non-magnetic) matter between the surfaces, whereas the magnetic force would tend to be concentrated in the vicinity of magnetic (and therefore conducting) protuberances. Tests with partially contaminated contacts have yielded gravitational and magnetic curves much more widely separated than those in the graph.

If, instead of plotting contact resistance against contact pressure, we plot it against the lateral force necessary to overcome the static friction between the contact surfaces, the difference between the two curves appears in general to be still present, although less marked.

It is thought that the effect described may have useful applications[3] in the field of light-current contacts, and also that it may repay investigation by those interested primarily in the frictional characteristics of sliding surfaces.

Elastic Deformation and the Contact of Surfaces

The friction, wear and electrical contact resistance of surfaces in stationary or sliding contact have been interpreted in terms of the real area of contact between the surfaces formed by the deformation of the material in the regions where they touch[1]. In general, it is to be expected that the total real area of contact will be divided between a number of individual areas. Recently, the implications of such multiple-contact conditions have been considered by using simple models to represent the contacting surfaces. In this way Lincoln[2] has attempted to explain the variation with load of the friction of high polymers, and I have discussed the contact resistance and wear of nominally mating surfaces[3]. It is the purpose of the present communication to emphasize the physical concepts which are inherent in these treatments and to indicate some general considerations which are independent of the particular model used.

As in the work described by Lincoln, it will be assumed that the deformation is entirely elastic; but plastic deformation can be considered by similar methods. For a single contact, the area of contact is proportional to the two-thirds power of the load. For multiple-contact areas the physically important postulate is the assumed variation of the number and size of the individual areas with load. As extreme cases, one can assume that either the number or the average size of these contact areas remains constant. Unless physically unlikely assumptions are made, in the former the area of contact is again proportional to the two-thirds power of the load, and in the latter the area is proportional to the load. If (as in the models mentioned above) an increase in the load causes an increase in both the number and size of the individual contact areas, the method of dimensions shows that the total contact area A is related to the load P by a general equation of the form,

$$A = K(P/E)^n. \qquad (1)$$

E is the Young's modulus of the material of the two surfaces (assumed similar) in contact, and K is a constant depending on the model used; it must, however, have dimensions of (length)$^{(2-2n)}$. n, which also depends on the model, lies between 2/3 and unity and has values of 8/9 and 4/5 in Lincoln's model and my model respectively. It is unlikely that existing experimental evidence is sufficient to distinguish between these two and other possible models. However, this evidence (for example, of the friction of high polymers and of the contact resistance of flat metallic surfaces) does suggest that the effective area of contact is related to the load by a more general equation, such as (1) above, with values of n between 2/3 and unity. Hitherto these values of n have usually been taken to indicate a departure from elastic conditions. The common aim in the use of multiple contact models is to show that such values of n are perhaps explainable, in terms of a distributed contact area and load, without postulating a change in the mechanism of deformation.

An Approach to Palæometeorology

GEOLOGICAL data have long been employed in reconstructing climates of the remote past, while palæobotanists in particular have demonstrated the temperature conditions of certain areas at selected periods. Much of the more precise botanical and palæontological evidence relates to glacial and post-glacial times, for which successions of wetter and dryer and of cooler and warmer climates were well established. Recent work now suggests that it may be possible to indicate, for portions at least of the Pleistocene of north-west Europe and some other areas, the approximate intensity of rainfall, that is, rate of rainfall per unit of time, which characterized certain climatic episodes. Thus light is thrown on weather, as opposed to climate, in the geological past. It may be possible in due course to bring these studies into relation with theoretical discussions of cyclonic activity during the Pleistocene.

The new information comes from investigations of meandering valleys, that is, valleys which describe systematic curves far larger than the loops of the rivers which flow in them. The many hypotheses of the origin of meandering valleys cannot be discussed here, but it can be said that a number have ascribed them to powerful ancestral streams. Their features reproduce, on a large scale, those of an incised meandering stream-course.

The resemblance is now known to extend beyond the forms visible at the surface to those concealed beneath the flood-plain alluvium. Six valleys have so far been studied in detail. In each, the alluvium is contained in a large channel, which winds around the valley bends and has a bed-form appropriate to a meandering stream. The ratio of bed-widths between filled and present channels is of the order of 10 : 1.

Although much remains to be discovered about the ultimate cause of meandering, laboratory studies and measurement of natural streams combine to indicate that dimensions of meanders are related principally to stream discharge[1]. It seems reasonable to conclude, therefore, that the filled channels are the beds of large streams which eroded the valley bends, and which discharged much more water than the present streams, stage for stage.

As a first approximation, the discharge required to nourish streams capable of cutting the filled channels may be found from Lacey's well-known equation[2]:

$$P = 2{\cdot}67Q^{1/2},$$

where P is the wetted perimeter in feet and Q the discharge in cusecs. (It is realized that this equation raises a number of problems, but there seem good reasons for accepting it in the present connexion.) At the rates calculated, the whole of the present rainfall could be run-off, without loss, in some five days.

The order of rainfall intensity required to provide the calculated discharges, with the channels flowing at bankful, may be derived from the 'rational formula' of flood discharge:

$$Q_{\text{max.}} = 640\ CiM,$$

where C is a coefficient of run-off, i the rainfall intensity in in./hr., and M the catchment area in square miles. This equation is suitable for use only with small catchments, and gives high discharge values.

Assuming maximum and very rapid run-off, C becomes unity. The two equations may now be combined in the form

$$i = \frac{P^2}{4550\ M},$$

which gives the former rate of discharge (in terms of rainfall intensity) corresponding to a given size of channel and area of catchment. In the six basins investigated, calculated values of i range from 0·21 to 0·33 in./hr.

At the present day, falls of this order are likely to occur over limited areas on two to ten days a year. But since meandering valleys are widespread, for example, in southern England and France, they would appear formerly to have been common and extensive.

Superficial deposits provide the chief means of dating the filled channels and the rivers which once occupied them. Some meandering valleys date back well into the Pleistocene; but the actual channels studied are all later than the last local glaciation, where they lie within the extreme limits of ice. Fossils from the alluvial fill have been identified as of extant species; the deposits are not promising material for pollen analysis. Converging evidence of an indirect or inferential kind suggests that some at least of the channels were still occupied by large rivers as late as the assumed end of the Pleistocene, that is, 10,000 years ago.

Young Morainic Topography in Holderness

IN 1951, A. Farrington and G. F. Mitchell published their observations during a visit to the glacial drifts of eastern England[1]. In their own words, they had "spent several days in the district mapping in outline the young topography north of Flamborough Head . . . Beacon-Hill and the mounds in Holderness at Kelk, North Frodingham and Brandesburton were also examined. . . . The authors have not seen any young morainic topography on the east coast of England south of Flamborough Head".

During spring–autumn of 1952, I carried out a geomorphological investigation of Holderness and adjacent parts of east Yorkshire and north-east

Lincolnshire. Eight recessional stages of the ice front could be established, starting with the marginal drainage channels in the Yorkshire and Lincolnshire Wolds, which had already been partially described by G. de Boer[2]. The glacial relief of western Holderness was found to be very mature indeed. A more conspicuous end-moraine, though still with a rather smooth surface, was traced from Haisthorpe via Kelk, North Frodingham, Routh and Wawne to Sutton, with corresponding esker systems near Kelk and Brigham-Brandesburton. A very different young morainic topography occurs, however, to the east of a line from Ulrome via Brandesburton, Skirlaugh, Preston, and Keyingham to Easington. Here are two high end-moraine ridges, one passing through Bewholme, Rise, Sproatley, Keyingham and Dimlington, and the other following the coast from Atwick via Mappleton, Grimston, Patrington to Holmpton, both with many kettle-holes filled with post-glacial lacustrine deposits not covered by solifluxion material. The ridges are traversed in the east – west and north-east – south-west direction by subglacial valleys, the best developed of which is the valley of Hornsea, with the "Rinnensee" of Hornsea Mere and the corresponding outwash fan of Leven still preserved.

Comparing all these features with the young morainic topography in north-east Germany, I am convinced that the last glaciation (Würm–Weichsel–Wisconsin) did not stop north of Flamborough Head, but extended with an ice lobe to eastern Holderness. The full results of the investigation will be published shortly.

Wilberforce and Huxley on Evolution

It was a famous moment in the history of science when, during the discussion of Darwin's theory of evolution at the British Association meeting at Oxford in 1860, Bishop Wilberforce turned to T. H. Huxley and asked him whether he claimed descent from an ape on his father's or his mother's side.

The actual words of Huxley's reply are not known; in the excitement, members of the audience noted different points, and two or three versions appear in the biographies and histories. The main source of our information, his son Leonard Huxley, wrote "most unluckily, no contemporary account of his own exists of the encounter"[1].

Such an account does, however, exist in a letter written to Dr. Dyster within a few months of the meeting, on September 9, 1860, and now preserved in the collection of Huxley Papers at the Imperial College of Science and Technology, London. The style of the quotation has the authentic tone: the putting his opponent in the wrong from the start, the use of antithesis, the long complex build-up to a dramatic pause, and then the final swift and decisive swoop. Considering also the accuracy with which Huxley was able to recall the details of what he had once formulated in his mind, it seems likely that this letter contains as nearly correct a record as we shall ever possess.

"When I got up I spoke pretty much to the effect—that I had listened with great attention to the Lord Bishop's speech but had been unable to discover either a new fact or a new argument in it—except indeed the question raised as to my personal predilections in the matter of ancestry—That it would not have occurred to me to bring forward such a topic as that for discussion myself, but that I was quite ready to meet the Right Rev. prelate even on that ground. If then, said I, the question is put to me would I rather have a miserable ape for a grandfather or a man highly endowed by nature and possessing great means and influence and yet who employs those faculties and that influence for the mere purpose of introducing ridicule into a grave scientific discussion—I unhesitatingly affirm my preference for the ape.

"Whereupon there was unextinguishable laughter among the people, and they listened to the rest of my argument with the greatest attention . . . I happened to be in very good condition and said my say with perfect good temper and politeness—I assure you of this because all sorts of reports [have] been spread about e.g. that I had said I would rather be an ape than a bishop, etc."[2].

I am indebted to the Governors of the Imperial College for permission to publish this extract.

Early Record of Temperature-Control in Distillation

We have recently published a study[1] of Johannes Banfi Hunyades (1576–1650), a Hungarian who about 1645 was professor of hermetic philosophy and mathematics at Gresham College, London.

MS. Sloane 1139 (British Museum), much of which was written by Jonathan Goddard, Gresham professor of physic from 1655, gives an account of the process adopted by Hunyades for distilling oil of amber. It contains the observations:

f.16r. "We observed yt in strong boyling to destill at the first in the 20 degree and at the last in the 40 degree."

f.18r. "dom Hunniades destilled it in the 6 and 4 degree."

These statements appear to constitute the earliest record of temperature measurement in distillation: we at any rate cannot interpret them in any other way. Hunyades died in 1650, and his process is likely to date from a period some years earlier. How, then, did he measure the temperature? Scarcely, we would think, with an air-thermometer of the types recorded by Galileo, Sanctorius or Fludd. Are we to suppose that he had a sealed thermometer of the type made for Ferdinand II, Duke of Tuscany, in 1641?

F. SHERWOOD TAYLOR

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 16

Institute of Metal Finishing (at Burlington House, Piccadilly, London, W.1), at 6 p.m.—Demonstration of Research and Control Technique in Electrodeposition.

Tuesday, November 17

Society of Chemical Industry, Agriculture Group (joint meeting with the Crop Protection Panel, in the Chemistry Lecture Theatre, Royal College of Science, Imperial Institute Road, London, S.W.7), at 2.30 p.m.—Symposium on "Grassland Management" and The Treatment of Turf".

Bedford College (at Regent's Park, London, N.W.1), at 5.15 p.m. —Prof. C. Daryll Forde: "Development of the Native Culture of West Africa" (Stevenson Lecture).*

Chadwick Public Lecture (at the Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W.1), at 5.30 p.m.—Dr. John A. Logan, in collaboration with Dr. R. P. Burden: "The Public Health Significance of Environmental Control by Engineering Means".*

Institute of Physics, Electronics Group (at 47 Belgrave Square, London, S.W.1) at 5.30 p.m.—Dr. A. S. Baxter: "Electron Multipliers".

Institution of Electrical Engineers, Measurements Section at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. A. H. M. Arnold: 'Alternating-Current-Instrument Testing Equipment".

Physical Society, Low Temperature Group (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5 30 p.m.—Dr. R. Kekwick and Dr. R. Strickland-Constable: "Freeze Drying".

British Ornithologists' Union (in the Lecture Hall, British Museum (Natural History), Cromwell Road, London, S.W.7), at 5 p.m.—Annual Scientific Meeting. Mr. Peter Scott: "Ornithological Results of a Journey to Tierra del Fuego and the High Andes", followed by a film on the Bird Life of Patagonia.

Royal Institute of Chemistry (joint meeting with the Battersea Polytechnic Chemical Society, at the Battersea Polytechnic, London, S.W.11), at 7 p.m.—Mr. W. S. Wood: "The Manufacture and Uses of Hydrogen Peroxide".

Wednesday, November 18

Postgraduate Medical School of London (at Ducane Road, Shepherd's Bush, London, W.12), at 2 p.m.—Prof. F. G. Young, F.R.S.: "Some Aspects of the Endocrine Control of Carbohydrate Metabolism".* (Further Lecture on November 19.)

Royal Meteorological Society (at 49 Cromwell Road, South Kensington, London, S.W.7), at 5 p.m.—Scientific Papers.

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Mr. P. T. Bauer: "Statistics of Statutory Marketing in West Africa, 1939–51".

Eugenics Society (at the Rooms of the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. G. Aird Whyte and Dr. C. P. Blacker: "Possible Future Activities of the Eugenics Society".*

Royal Microscopical Society (at Tavistock House South, Tavistock Square, London, W.C.1), at 5.30 p.m.—Prof. F. W. Jane: "The Frontiers of the Plant and Animal Kingdoms".*

Royal Institute of Chemistry, London Section (at King's College, Strand, London, W.C.2), at 6 30 p.m.—Annual General Meeting.

Thursday, November 19

University College, London (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. W. B. Emery: "Excavations at Sakkara (Egypt) in 1953".*

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4 30 p.m.—Mr. R. Berman, Prof. F. E. Simon, F.R.S., and Mr. J. M. Ziman: "The Thermal Conductivity of Diamond at Low Temperatures"; Mr. F. C. Champion: "Variations in the Texture of Diamonds".

Institution of Mining and Metallurgy (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. W. R. Cheetham and Mr. H. W. Inett: 'Factors Affecting the Performance of Percussive Drills"; Mr. D. C. J. Squirrell: "Surface Diamond Drilling Problems and Practice in the Copperbelt Area of Northern Rhodesia".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. N. Woodhead and Mr. R. D. Tweed. "A Consideration of the Freshwater Algae of Sierra Leone"; Mr. G. Owen Evans: "An Introduction to the External Morphology and Biology of the British Pseudoscorpiones (Arachnida)"

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting. Prof. W. W. Rogosinski · "Extremum Problems for Real Polynomials and Trigonometrical Polynomials".

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. F. Sims: "The Wear of Carbon Brushes at High Altitudes".

Research Defence Society (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Sir James Learmonth: "The Surgeon's Debt to Animal Experiment". (Twenty-Second Stephen Paget Memorial Lecture.)

Society of Chemical Industry, Road and Building Materials Group (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6 p.m.—Mr. H. H. Nevard: "Reasons and Methods for Timber Preservation".

Royal Aeronautical Society (in the Library, 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. A. W. Babister: "Aircraft Stability and Control".

Chemical Society (in the Lecture Theatre, Institution of Civil Engineers, Great George Street, London, S.W.1), at 7.30 p.m.—Prof. A. Tiselius (Uppsala): "Some Applications of the Separation of Large Molecules and Colloidal Particles" (Centenary Lecture).

Royal Society of Tropical Medicine and Hygiene (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 7.30 p.m.—Laboratory Meeting; Chairman: Dr. Norman White.

British Institute of Radiology, incorporated with the Rontgen Society (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 8 p.m.—Dr. Sheila T. Callender and Dr. John Badenoch: "The Use of Radioactive Iron in the Investigation of Anaemia"; Dr. H. H. Belcher, Mr. I. G. F. Gilbert and Dr. L. F. Lamerton: 'Experimental Studies with Radioactive Iron".

Society of Public Analysts and Other Analytical Chemists, Biological Methods Group (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 8 p.m.—Dr. Chester I. Bliss (U.S.A.): 'The Standardization of a Drug in Production as Illustrated by Adrenal Cortical Extract".

Friday, November 20

Physical Society (at the Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Prof. W. Sucksmith: "Some Magnetic Measurements—Techniques and Applications"; Prof. F. C. Williams: "Cathode-Ray Tube Storage for Digital Computers".*

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Sir Richard Southwell, F.R.S. "Relaxation Methods: a Retrospect" (Thomas Hawksley Lecture).

Institute of Physics, Industrial Radiology Group (at 47 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. R. Meakin. "Scattered Radiation".

Royal Holloway College (at Englefield Green, Egham, Surrey), at 8.15 p.m.—Mr. F. I. G. Rawlins: 'The Work of the Scientific Department of the National Gallery".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. Kenneth P. Oakley: "Dawn of Man in South Africa".

Friday, November 20—Saturday, November 21

Institute of Physics, X-Ray Analysis Group (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2).—Autumn Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chemist (with university degree or equivalent in chemistry, and experience in some branch of industrial chemistry) in the Divisional Analytical Laboratory, Birmingham and District Division—The Divisional General Manager, West Midlands Gas Board, Gas Offices, Edmund Street, Birmingham (November 21).

Chief Engineer to the North Western Electricity Board—The Establishment Officer, The North Western Electricity Board, Cheetwood Road, Manchester 8 (November 21).

Lecturer (with university degree or equivalent qualifications, and sound fundamental knowledge of physical chemistry) in Ore-dressing in the Department of Mining, Metallurgical and Chemical Engineering, South Australian School of Mines and Industries—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (November 21).

First Assistant Laboratory Engineers (3) (with university degree in civil engineering, physics or chemistry, and corporate members of a recognized professional institution), to take charge of one of the laboratory sub-sections dealing with (*a*) soils mechanics, (*b*) tar, bitumen and coated materials, (*c*) cement and concrete—The County Engineer and Surveyor, County Hall, Wakefield (November 23).

General Manager (with high administrative ability and considerable practical experience of the utilization of fuel and power, and preferably with a recognized technical qualification in the field of combustion and thermal engineering) of the National Industrial Fuel Efficiency Service—The National Industrial Fuel Efficiency Service, Thames House South, 6th Floor, Millbank, London, S.W.1 (November 24).

University Demonstrator in Botany, to be responsible for teaching genetics in collaboration with the professor—Prof. C. D. Darlington, The Department of Botany, The University, Oxford (November 24).

Plant Layout Engineer (qualified engineer, with a comprehensive knowledge of the layout of reconditioning workshops and of the plant, machinery, equipment and services connected with them) in the Engineering Branch of the Production Department in London, to assist in the planning and design of a number of modern workshops which are required in the coalfields for the reconditioning of coalmining and other equipment and plant, and for a small amount of specialized manufacture—The National Coal Board, Establishments (Personnel) Hobart House, Grosvenor Place, London, S.W.1, quoting TT/701 (November 27).

Research Assistant in Psychology—The Registrar, The University, Manchester (November 28).

Scientific Officers (2) (with first- or second-class honours degree in civil engineering) in the Department of Scientific and Industrial Research, Road Research Laboratories, Harmondsworth, West Drayton, Middlesex, for (*a*) research on bituminous road materials and associated machinery, and (*b*) research on soil mechanics and earth moving machinery—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting E.396/53 (November 28).

Assistant in Experimental Pharmacology—The Secretary of University Court, The University, Glasgow (November 30).

Lecturer in Social Anthropology—The Registrar, The University, Manchester 13 (November 30).

Lecturers or Assistant Lecturers (2) in Physics at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (November 30).

Lecturer or Senior Lecturer in Chemical Pathology—The Secretary, Royal Veterinary College and Hospital, Royal College Street, London, N.W.1 (December 1).

Mechanical Engineer (with degree in mechanical engineering or A.M.I.Mech.E.) **in the Public Works Department** (Development Establishment), Northern Rhodesia, to assist the Senior Mechanical Engineer in the administration of Government Mechanical Workshop Organization—The Director of Recruitment (Colonial Service), Colonial Office, London, S.W.1, quoting CDE.112/3/04 (December 2).

Research Officers (2) (with first-class honours degree, with physics as a major subject or equivalent qualifications, and preferably with research experience in astrophysics or optics) in the Commonwealth Scientific and Industrial Research Organization, Division of Physics, National Standards Laboratory, Chippendale, N.S.W., Australia, to carry out periodical observations at a station to be erected on the Australian Alps—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 770/83 (December 5).

Scientific Officer (with first- or second class honours degree in natural science with zoology as principal subject, or equivalent qualifications) **at the Ministry of Agriculture and Fisheries**, Tolworth, Surrey, for research on grey squirrels—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.366/53A (December 5).

Research Officer (with at least an honours degree in pure mathematics, and either postgraduate specialist training in mathematical statistics or research experience in applied statistics in the biological or social sciences) **in the Mathematical Statistics Section** of the National Institute for Personnel Research, Johannesburg—South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, December 7).

Plant Pathologists (graduates from a recognized university with some postgraduate experience and training in plant pathology) with the Tobacco Research Board of Southern Rhodesia—The Director, Tobacco Research Board of Southern Rhodesia, P.O. Box 1909, Salisbury, Southern Rhodesia (December 31).

Lecturer in Pure Mathematics—The Secretary, Queen's University, Belfast (February 15).

Rutherford Scholar (graduate of a university within the British Commonwealth) for research in any branch of the natural sciences, but some preference will be given in favour of candidates who propose to work in experimental physics—The Assistant Secretary, Royal Society, Burlington House, Piccadilly, London, W.1 (February 15).

Agricultural Officers (with degree in agriculture and at least two years postgraduate training or experience in agriculture) in the Colonial Territories (at present mainly in East and West Africa and Fiji)—The Director of Recruitment (Colonial Service), Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.68/01.

Botanist (Plant Breeder) (with good honours degree in botany with training in plant breeding, and some knowledge of statistics as applied to field experiments, and at least two years postgraduate experience) at Rokupr Rice Research Station, Sierra Leone—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.87/15/01.

Chemist (with honours degree in chemistry or chemical engineering, or equivalent qualifications) to assist in problems associated with the treatment of radioactive materials, purification of drinking water supplies, general water treatment and general water service—The Establishment Officer, Atomic Energy Research Establishment, Harwell, Berks, quoting 2/103/6.

Civil Engineer (with degree in civil engineering, A.M.I.C.E., A.R.I.C.S., registered architect or equivalent), with the Ministry of Supply at London, S.E.9, to be responsible under direction for preparation of designs, specifications, and estimates for building and civil engineering in explosives and filling factories—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting E.484/53A.

Entomologist (with first- or second-class honours degree in an appropriate subject or equivalent qualifications) in the Colonial Insecticide Research Unit, Ministry of Supply Chemical Defence Experimental Establishment, Porton, Wiltshire, to conduct research on entomological problems relating to the application of insecticides—The Under-Secretary of State, Research Department (S.610), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

Experimental Officers (2) and Assistant Experimental Officers (2) (with qualifications equivalent to pass degree in pure or applied science, and ability to prepare articles describing scientific and technical work in a simple and attractive manner) in the Department of Scientific and Industrial Research, Headquarters Office—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.277/53A.

Graduate (with degree in science, technology or engineering) **in the Fuel Technology Section** of the Physics Department, to investigate problems associated with heating of steel in industrial furnaces—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "Fuel".

Physicist or Metallurgist (with at least H.S.C. (Science) or equivalent, but degree in metallurgy or physics may be an advantage) at the Atomic Energy Research Establishment, Harwell, for work on X-ray diffraction, involving responsibility for X-ray work of Metallurgy Division—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.280/53A.

Senior Scientific Officer (with first- or second-class honour degree in chemistry or equivalent) **in the Mineral Resourc Division**, Colonial Geological Surveys, Imperial Institute, Londo S.W.7, to take part in a special investigation needing a sound know ledge of mineral chemistry and a good general experience of miner analysis—The Ministry of Labour and National Service, Technic and Scientific Register (K), 26 King Street, London, S.W.1, quotin F.434/53A.

Senior Scientific Officer (with honours degree in mechanic engineering, and preferably with experience in agriculture), as hea of section engaged on testing, research and development in connectio with farm mechanization; a **Scientific Officer** (with honours degre in mechanical engineering) to assist the above S.S.O.; and a **Senio Assistant** (Scientific) to assist in the maintenance and operation o electronic strain measuring and recording equipment, with the Britis Society for Research in Agricultural Engineering—The Scottis Machinery Testing Station, Howden, Mid-Calder, Midlothian.

PERMUTIT

Ion Exchange Materials

The use of Permutit Ion Exchange Materials in many roles distinct from water treatment, has resulted in the development of numerous new industrial processes giving improved results and lower running costs. Some materials now available are —

ZEO-KARB. A sulphonated coal product containing both strong and weak acid groups.

ZEO-KARB 215. A nuclear sulphonic acid resin containing also hydroxyl groups.

ZEO-KARB 216. A resin containing weak acid groups of the carboxyl type.

ZEO-KARB 315. A sulphonic acid resin particularly stable up to 100° C.

ZEO-KARB 225. A unifunctional, high capacity sulphonic resin in bead form.

BIO-DEMINROLIT. A mixed cation and anion exchange resin of high stability for demineralisation in a single column.

DE-ACIDITE E. A medium basicity high capacity anion exchange material.

DE-ACIDITE F. A very high basicity anion exchange material suitable for absorption of very weak acids.

DECOLORITE. A resin of high porosity for removing colour from solutions.

RESIN MEMBRANES. For special purposes, many of these materials can be supplied as membranes in the form of rods, discs and thimbles.

The Permutit organisation is continually developing new Ion Exchange Materials, and new methods of using them. Its Research Laboratory is ready always to co-operate in the solution of your problems.

PERMUTIT ION EXCHANGE MATERIALS — MADE IN BRITAIN BY BRITISH LABOUR

LECTURES AND COURSES

GRESHAM COLLEGE

BASINGHALL STREET, LONDON, E.C.2

Four lectures by Professor H. Hartridge, M.A., M.D., Sc.D., M.R.C.P., F.R.S. (Gresham Professor in Physic), on "The Physiology of Vision—Part 3" on Monday to Thursday, November 16 to 19, 1953.

The lectures are free, and begin at 5.30 p.m.

OFFICIAL APPOINTMENTS

The engagement of persons answering these advertisements must be made through a Local Office of the Ministry of Labour or a Scheduled Employment Agency if the applicant is a man aged 18 to 64 inclusive, or a woman aged 18 to 59 inclusive, unless he or she, or the employment is excepted from the provisions of the Notification of Vacancies Order, 1952.

COMMONWEALTH of AUSTRALIA

The Commonwealth Scientific and Industrial Research Organization invites applications to the undermentioned positions of Research Officer on the staff of its Minerals-Utilization Section, Division of Industrial Chemistry, Fishermen's Bend, Melbourne, Victoria. Appointment 590/460. Duties: To undertake physico-chemical studies of systems of importance in the utilization and chemical processing of minerals and their derivatives. Qualifications: University honours degree in science, with chemistry as a major subject, or equivalent qualifications. Some post-graduate experience in electro-chemistry would be an additional qualification. Appointment 590/461. Duties: To undertake general investigations on chemical derivatives of certain Australian minerals. Initially the work will be concerned with the pure and applied chemistry, and separation techniques, of zirconium and hafnium compounds. Qualifications: University honours degree in science, with inorganic or physical chemistry as a major subject. Experience in the field indicated is not essential, but some knowledge of high vacuum techniques would be an advantage. Salary: Within the range of Research Officer, £A.854 to £A 1,262 per annum (actual), thirteen increments. Salary includes a cost-of-living adjustment of £A 198 per annum. Fare to Australia (including those of wife and family) will be paid. Appointee may be granted superannuation privileges.

Applications, referring to the appropriate appointment number, and stating full name, place and date of birth, nationality, marital state, present employment, particulars of qualifications and experience, and of war service, if any, accompanied by names and addresses of at least two persons willing to act as referees, if so required, and copies of not more than four testimonials, should reach the undersigned, from whom further particulars may be obtained, by December 12, 1953.

J. E. CUMMINS,
Chief Scientific Liaison Officer
Australian Scientific Liaison Office,
Africa House, Kingsway, London, W.C.2.

H.M. COLONIAL SERVICE

Applications are invited for the following post: Research Officer, Maize Rust Research Scheme, Nigeria. Candidates must possess at least good second-class honours degree in botany, with training in genetics, and have had at least two years' postgraduate experience in plant breeding, preferably in cereals, ideally in maize. Appointment on probation in Colonial Research Service in Scientific Officer scale (£400 to £650 per annum), Senior Scientific Officer scale (£750 to £950 per annum), Principal Scientific Officer scale (£1,000 to £1,375 per annum), or Senior Principal Scientific Officer scale (£1,500 to £1,750 per annum), according to age and experience. Allowances as follows also payable: Overseas research allowance, £250 to £400 per annum; pay addition, 10 per cent of first £500 basic salary, 5 per cent of next £500 basic salary, 2½ per cent of next £500 basic salary, flat rate £100 per annum on basic salary £1,500 to £1,750; outfit allowance, £60 on first appointment. Contributory superannuation scheme. Taxation at local rates. Government quarters, when available, at rental of 10 per cent of basic salary (maximum £150 per annum). Free passages for officer, wife and children under 13 years of age on appointment and leave.

Apply, in writing, to the Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, giving briefly age, qualifications and experience. Mention the reference number 27059/520.

H.M. COLONIAL RESEARCH SERVICE

WEST AFRICA

Applications are invited from male candidates for appointment as Senior Scientific Officer or Scientific Officer, to undertake duties of Veterinary Research Officer in the West African Institute for Trypanosomiasis Research. Duties consist of research, in the laboratory and in the field, on trypanosomiasis as it affects cattle and other domestic animals. Investigations at present in progress include studies on the chemotherapy and chemoprophylaxis of animal trypanosomiasis, immunological and pathological studies; tolerance of indigenous breeds of cattle to trypanosomiasis; studies on the various trypanosomes pathogenic to domestic animals and the factors governing their transmission through the insect vector. Exceptional facilities for original research are available at the Institute's modern and well-equipped laboratories. Salary scale for Senior Scientific Officer is £750 by £30 to £950 a year; plus overseas research allowance of £490 a year on salaries up to £780; £510 a year on salaries of £780 to £869; and £530 a year on salary over £870 a year. For Scientific Officer the salary scale is £400 by £25 to £450 by £30 to £650 a year (a candidate qualified M.R.C.V.S. after a five-year course enters at £525 a year if 24 years of age, and £500 a year if under). Overseas research allowance of £380 a year on salary below £525; £460 a year on salaries between £525 and £615; and £490 a year on salaries of £615 to £780 a year. Increments for experience and qualifications. A car allowance is payable of £140 per annum, plus a mileage allowance. Outfit allowance £60. Modern furnished quarters suitable for either single or married officer are available at rental of up to 10 per cent of basic salary. Tours of service vary from twelve to twenty-four months (usually fifteen to eighteen months), and leave is earned at the rate of one week for each completed month of duty. Free passages for officer, wife and children on appointment and on leave. The officer would normally have his headquarters at Vom, Plateau Province, Northern Nigeria (altitude 4,000 ft.), where the climate is equable and healthy and where there are many amenities, including shops, clubs, cinemas and facilities for games, shooting, etc. Candidates must have veterinary qualifications registrable in the United Kingdom, with basic training in haematology, pathology, chemotherapy and the principles of immunology plus, in the case of appointment as Senior Scientific Officer, at least three years' postgraduate experience.

Application forms can be obtained from the Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1 (quoting reference No. CDE 67/89/01).

UNIVERSITY OF DURHAM

Applications are invited for the Chair of Organic Chemistry tenable at King's College, Newcastle-upon-Tyne. The appointment will date from October 1, 1954. The salary will not be less than £1,750 per annum, plus family allowance and F.S.S.U.

Further particulars may be obtained from the undersigned, with whom twelve copies of applications, containing names of three referees, should be lodged not later than December 7, 1953. Candidates outside the British Isles may send one copy.

E. M. BETTENSON,
Registrar.

University Office,
46 North Bailey, Durham.

UNIVERSITY OF ADELAIDE

AUSTRALIA

Applications are invited for appointment as Reader in Pathology. Salary range £A.1,250 by £A.40 to £A 1,450 plus cost-of-living. The cost-of-living adjustment is at present £A 244 8s. and it is not thought that there will be any change in that figure in the foreseeable and near future. The Reader will be required to undertake teaching and research in the Department of Pathology, and to assist in the autopsy work which the department conducts for the Royal Adelaide Hospital, the main teaching hospital.

The original application and original supporting documents should be sent to the Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (from whom conditions of appointment are obtainable), and two copies forwarded by air to the undersigned, to reach him not later than January 31, 1954.

A. W. BAMPTON,
Registrar.

LEEDS COLLEGE OF TECHNOLOGY

Principal: C. Chew, M.Sc.Tech., F.R.I.C.

DEPARTMENT OF CHEMISTRY AND BIOLOGY

Applications are invited for the post of L turer in Physical Chemistry in the above Depa ment, duties to commence on January 1, 1954.

Applicants should possess a good honours de gree, together with postgraduate experience physical chemistry and suitable teaching expe ence.

The post will be graded as Lecturer on t scale £940 by £25 to £1,040 per annum.

Further particulars and form of applicatio to be returned by November 25, 1953, may b obtained by sending a stamped, addressed foo scap envelope to the Chief Education Offic Education Offices, Leeds, 1.

ROYAL VETERINARY COLLEG AND HOSPITAL

(UNIVERSITY OF LONDON)

Applications are invited for a Lectureship Senior Lectureship in Chemical Pathology. Sala scales: Lecturer £600 by £50 to £900, £900 £50 to £1,150; Senior Lecturer £1,000 by £ to £1,250. Initial placing according to qualific tions and experience. Superannuation benef and children's allowances.

Application forms, obtainable from the Secr tary, should reach him not later than Decemb 1, 1953, at the Royal Veterinary College an Hospital, Royal College Street, London, N.W

TRANSVAAL PROVINCIAL ADMINISTRATION

UNION OF SOUTH AFRICA

VACANCY FOR PHYSICIST AT THE PRETORIA HOSPITAL, PRETORIA

Applications are invited for the vacancy c Physicist on salary-scale £900 by £50 to £1,20 per annum at the Pretoria Hospital, Pretori Applicants must be in possession of at least th B.Sc. degree with physics as a major subject, bu preference will be given to persons with a B.Sc honours or an M.Sc. degree with satisfactor experience. Applicants must state specifically th nature and length of experience gained in th field of X-ray physics including radio-isotopes, etc In addition to the salary a cost-of-living allow ance at rates prescribed from time to time, payable. The present rate is £100 per annum fo single persons, and £320 per annum for marri persons. The successful applicant will be ap pointed in a permanent capacity in terms of, an subject to, the provisions of the Public Hospital Ordinance, 1946, as amended, and the regula tions framed thereunder will be required to sub mit satisfactory certificates of health and birth The Provincial Administration is prepared t meet the cost of sea passage and rail fare from Cape Town to Pretoria to an amount not t exceed £100 (one hundred pounds). Successfu applicant will be required to enter into a con tract of service with the Provincial Administra tion for a period of three years. The sum advanced or proportion thereof shall be refunde immediately by the appointee if he terminate his contract before the expiration of the three years. The amount of the refund shall be calcu lated in the following manner, if the terminatio takes place (a) within the first year after assum ing duty, the full amount of the passage mone and train fare; (b) after one year of service bu before completion of two years' of service, two-thirds of the passage money plus train fare; (c) after two years' of service but before the completion of three years' of service, one-third of the passage money plus train fare.

Applications must be submitted to the Medica Superintendent, Pretoria Hospital, Pretoria, and must reach him on or before December 31, 1953. Application forms and the forms of agreement are obtainable from the Staff Clerk, Room 102, South Africa House, Trafalgar Square, London, W.C.2.

BIRKBECK COLLEGE

(UNIVERSITY OF LONDON)

Applications are invited for the post of Assistant Lecturer in Physics. Salary £500 by £50 to £600 per annum.

Further particulars and forms of application should be obtained from the Secretary, Birkbeck College, Malet Street, London, W.C.1, to whom completed forms should be returned not later than November 28, 1953.

MONOSCOPE

The G.E.C. Monoscope is a secondary emission type of picture signal generator tube.
It offers the simplest means of providing a video test signal, which is obtained by scanning a fixed pattern reproduced on a target plate within the tube.
The derived picture may consist of either line or half tone information or both in combination, with a maximum vertical definition of 800 lines. The picture plate dimensions are 98 × 74 mm giving the standard aspect ratio of 4 × 3.
The standard pattern is test card "C", but alternative patterns can normally be supplied to meet special requirements.

The discovery of chemical elements from the stone-age hearth to the cyclotron in

J. NEWTON FRIEND'S

MAN AND THE CHEMICAL ELEMENTS

"Written in a pleasantly discursive vein the book has a sound scientific basis and is well documented and indexed . . . it contains a wealth of apposite chemistry, history, lore and anecdote, presented in a manner likely to appeal equally to the scientific worker and layman."—NATURE.

That the best approach to science is through its history is a fact widely recognized and demonstrated by the frequent appearance of historical questions in academic and professional examinations. The author of this fascinating story of man and the chemical elements has compiled a history which is by no means "dry"; he has spiced the text with a fund of curious and amusing information which detracts nothing from its sound fundamental approach to the subject. It is an account of undoubted value to the scientist for his background reading and of absorbing interest to those studying man and his technical progress.

FUEL CONSERVATION IN BRITAIN

IN recent years two subjects have been constantly before the British public to such an extent that a state of saturation has been reached and the people have become almost indifferent to incessant exhortation. One is productivity and the other is fuel. In some respects they are both as important to our welfare as the air we breathe. Indeed, the air itself has recently come into the orbit of popular clamour as the result of the unfortunate occurrences that followed an atmospheric inversion in December last. All these matters are linked up with fuel conservation, the subject of a recent brochure published by the British Productivity Council and addressed to the Anglo-American Council on Productivity*. The publication, a somewhat detailed document of more than one hundred pages, is a report on a visit made to the United States in January of last year by a British team to study the conservation of fuel, heat and energy in the United States of America. This visit was planned with the view of improving the efficiency of fuel utilization in British industry, and indicating ways and means by which a national fuel policy might be developed.

The report contains much interesting material, for example, in relation to such matters as the comparison of the fuel resources in the United States and Great Britain, the relationship between energy and man-power, the high rate of consumption of power per head of population in comparison with that in Britain, associated to some degree with the high costs of labour in the United States, combined heat and power supply, so-called 'packaged' boilers, the six hundred heat pumps installed in thirty-nine American States, and the measures taken by the Americans to attempt to control their smoke emission. In general, however, the major substance of the report has been well known for at least a decade, and in some respects for a generation. Accordingly, the mischievous critic might be tempted to suggest that the report could have been written without the visit to the United States having been undertaken. Nevertheless, the authors deserve commendation for a painstaking review, and not the least for the clear and concise summary and recommendations, much to be welcomed in these days when the scientist and the industrialist have so much to read in order to keep abreast of modern developments. Many of the recommendations should receive general support; but others are open to criticism mainly for the reason that, though they may state desirable objectives, they give little information that is new which would enable these objectives to be achieved. Thus there is a plea for the removal of the nationalized industries from the influence of party politics, but no practicable suggestions as to how it may be done. Again, there is a call for co-ordination of the coal, gas and electrical industries by a directive composed of

---

* British Productivity Council. Productivity Report: Fuel Conservation. Report of a visit to the U.S.A. in 1952 of a Specialist Team on the Conservation of Fuel, Heat and Energy. Pp. xii+102+8 plates. (London: British Productivity Council; Washington, D.C.: Office of Technical Services, Department of Commerce, 1953.) 5*s*.

"men best fitted for the job". This phrase may be interpreted by various types of opinion, as meaning 'jobs for the boys', or 'overlords', or 'suitability based on experience and achievement'. The recommendations also call for a government statement on policy. Policy may be interpreted as the motives that govern administrative action, and therefore must be essentially a matter of day-to-day concern. One cannot expect, therefore, a wise administrator to be other than cautious in stating policy in advance; and least of all to put important administrative functions in the hands, say, of a commission as recommended in the report. The larger the organization the less efficient it must become, since human relations depend upon human beings, and there is approached that state of society envisaged by Wells, in which man becomes the slave of the machine he has created.

The reference to financial incentives in the form of tax relief, rather than loans, should in our opinion have had pride of place. Indeed, it is the only recommendation that could have any real effect in furthering fuel efficiency in those branches of British industry in which the cost of fuel is a secondary matter.

It is well known that where fuel is an important factor in costs of production, considerable attention is given to fuel practice. This feature of the problem has been overlooked in the report, as well as the remarkable contributions to fuel efficiency that have been made in these industries during the past generation. Indeed, in reading the report, the newcomer to the subject is almost left with the impression that fuel efficiency began with the Ridley Report. The real progress in these matters is made by those sections of industry and industrial and scientific research, the business of which it is to advance technical practice. Thus we have seen, during the past thirty years, considerable progress in the fuel aspects of the production of power, the manufacture of iron and steel, and the development of a whole host of new industries based on the by-products of coal, all having had outstanding results, not only in increasing world productivity but also in saving British coal. Arguments in committee, exhortation, publicity and even the best of salesmanship can be of small account in these matters in comparison with a major advance in practice based on scientific discovery, or even with the day-to-day efforts of the technologist or engineer concerned with such practice.

The problems discussed in the report are, however, of a sociological rather than a technical character, in so far as any effective action is concerned. Nevertheless, the general reader will be interested in much of the technical matter discussed. Thus the discussion of the development of dual-generating stations located in industrial areas is timely. There are pages of much interest on the more well-worn subjects of the developments to be looked for in the gas industry, the improvement of the education and status of stokers, the thermal insulation of buildings, the greater use of instruments and smoke abatement. Some controversial issues are raised in regard to the standardization and design of boilers. Whether the American model of the self-contained, automatically controlled oil-fired boiler of the 'packaged' pattern will meet needs where ostensibly the inferior grades of coal may be efficiently used is open to question. There is also a tilt at the railways of Britain in regard to the use of large coal for firing locomotives. This is thought to be a traditional practice rather than a rational one, and it is recommended that the judicious use of sized coal would be both desirable and useful. The last recommendation recalls a particularly British failing in all but the largest and most progressive elements of industry, namely, the gap between the production and application of a new discovery. This statement has been made time and time again; but progress is very slow. No new suggestion, however, emerges in the present juncture. Summing up, while the report may contain little that technical workers do not already know, it presents these topics in general terms which may help to bring them before the public and so prepare the ground for action.

PRECISION IN ASTROPHYSICS

The Outer Layers of a Star

By Prof. R. v. d. R. Woolley and D. W. N. Stibbs. (International Series of Monographs on Physics.) Pp. xi+307. (Oxford: Clarendon Press; London: Oxford University Press, 1953.) 40s. net.

Basic Methods in Transfer Problems

Radiative Equilibrium and Neutron Diffusion. By V. Kourganoff, with the collaboration of I. W. Busbridge. (International Series of Monographs on Physics.) Pp. xv+282. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 35s. net.

THE greater part of what is known about the sizes, masses and motions of the stars, about what goes on in their interiors and also about the diffuse matter outside them depends upon the detailed investigation of the radiation that the stars emit. All the features of this radiation are influenced by the processes occurring in the outer layers of the stars. Recalling these familiar facts, it is appreciated that any precision in our knowledge of the astronomical universe is to a major extent conditioned by the precision of our knowledge of the processes mentioned and of the parts they play in affecting anything that comes out of a star. The two books under review are concerned with these matters, that is, with the chief basis of precision in astrophysics. Thus there is ample justification for the elaboration in the treatments they present. To such justification must be added that of the inherent interest of the work itself.

The work is also of interest for physics in general and not only for astrophysics. As an example (outside the scope of these books) it may be mentioned that one of the three 'crucial tests' of Einstein's general relativity theory is concerned with the gravitational red-shifts of spectral lines. Despite past claims, it is now widely recognized that this matter is not yet settled and that it cannot be settled at the present stage of astrophysics. All the other agencies that affect the spectral lines can be assessed with sufficient accuracy to admit the application of Einstein's test only, if at all, after even greater elaboration of the astrophysical theory than that exemplified in these books.

With regard to "The Outer Layers of a Star" by Prof. R. v. d. R. Woolley and D. W. N. Stibbs, it is a pleasure to welcome a book from the Commonwealth Observatory of Australia, which, under Prof. Woolley's direction, has so rapidly become a leading centre of astronomical research. The topics dealt with include many to which Woolley himself has made numerous important contributions. The range of topics, mathematical and physical as well as astronomical, is exceedingly extensive, and the authors have selected them for varied reasons concerned with importance, with adaptation to astrophysical requirements, with bringing other accounts up to date (to 1950), and, very naturally, with their own particular interests. The common factor of all the work is its usefulness for further progress in the subject. Every item is the sort of thing that a working astrophysicist may need to know about at any moment, and he will be grateful to be able to turn to Woolley and Stibbs for a clear and concise account of it.

The main part of the book deals with the mathematical and physical theory of the transmission of radiation through a stellar atmosphere in radiative equilibrium. Chapter 9, on the photosphere, turns to problems in which mechanical equilibrium is also concerned, and these are further pursued in Chapter 10 on convection. Chapters 11 and 12 deal with the outermost regions of the solar atmosphere and, among other things, are noteworthy for giving probably the first 'text-book' account of the escape of radio radiation from a star. Most of the observations with which the theory is compared thus far are those for the sun; a final chapter deals with stars other than the sun. One regrets that it does not include a table of, say, temperatures, densities and linear depths (so far as these have been evaluated) for various optical depths for stars of various classes; the available information is often asked for, but appears not to have been collated in any standard text.

Many readers may be surprised to know that the exact solution in calculable form of the simplest significant problem of radiative transfer has been obtained completely only within about the past ten years. The problem concerns the transmission of radiation through a highly idealized atmosphere and was formulated by E. A. Milne more than thirty years ago. Moreover, until the exact solution was available, there were no reliable estimates of the accuracy of the various approximate solutions. The chief purpose of Dr. V. Kourganoff's book is to describe all the methods so far discovered for obtaining approximate and exact solutions of this one problem. As he says, this serves to illustrate most of the essential difficulties of the subject. Also, the methods form the basis for the solution of more general problems, and some ways in which they have been made to do so are summarized in the concluding chapter.

Dr. Kourganoff has contributed much to the theory which he here presents in such a well-digested form and with such illuminating insight. Clearly, Dr. I. W. Busbridge's collaboration has added substantially to the many merits of the book. To those whose primary interest is in transfer problems (of radiation or of neutrons) it will become indispensable. Its reading is also to be strongly recommended to those beginning research in theoretical astrophysics: in a subject where so much has to be attempted by the use of somewhat crude mathematics, this would be an excellent remedial exercise.

At the same time, those who do try to make progress by the cruder methods may seize the occasion to point to this book as illustrating the formidableness of the difficulties in using more refined mathematics for even the simplest of their problems.

The main part of the book is an exhaustive treatment of the theory outlined in the first three chapters of Woolley and Stibbs, which ought to be read first. Dr. Kourganoff's book is complementary to Chandrasekhar's "Radiative Transfer" (1950), as might be expected from its inclusion in the same series of monographs. In the latter book a smaller range of methods is applied to a much wider range of problems. The non-glossy paper used for the present volume makes it much pleasanter to read than some others in the series. W. H. McCrea

---

STATISTICAL METHOD IN BIOLOGICAL ASSAY

Statistical Method in Biological Assay

By Dr. D. J. Finney. Pp. xix+661. (London: Charles Griffin and Co., Ltd., 1952.) 68*s*. net.

THIS is the most comprehensive text-book which has so far appeared on statistical method in biological assay. Like all true scholars, Dr. Finney has endeavoured to give a thorough account of a particular branch of human knowledge. "My aim", he says modestly, "has been to develop the theory and methods as far as seem practicable at this time, and to show the unity of the various aspects of the subject", but the driving force behind the production of this able exposition is a great deal more than utilitarian. This explains its success. The book is written primarily for professional statisticians who wish to acquire a comprehensive knowledge of the subject; but it is intended also for use by four different categories of readers: the professional statistician desiring a short course in biological assay, the non-mathematical user of biological assays, the reader whether statistician, biologist or chemist who requires a general survey of the function of statistical science in biological assay, and the reader whose interest lies almost entirely in assays based on quantal responses. Suggestions are made for a first reading by each class.

After an introductory chapter dealing with the purpose, history and structure of biological assays and the role of international standards and statistical science in relation to them, direct assays are next discussed. In direct assays the amount of the drug under examination necessary to produce the characteristic response is observed directly in each animal used. The rest of the book deals with assays depending on measured responses (fourteen chapters) and on quantal responses (five chapters). The treatment is thorough with special attention to general principles and with copious well-chosen examples. The importance of statistical design is rightly emphasized.

The fourth, fifth and sixth chapters deal with parallel line assays and their efficiency, reliability and sensitivity. The seventh and eighth are concerned with slope-ratio assays. They are particularly good, and a tribute must be paid to the author here for the great part which his own work has played in the development of this part of the subject. There follow chapters on incomplete block designs, cross-over designs, multiple assays, the use of concomitant information, composite responses, the combination of estimates, and then the validity and choice of metameters. The sixteenth chapter is concerned with an illustration of a general method which can be used when the transformation which produces equality of variance in response at all dosage levels fails to produce a linear dosage response relation.

In considering assays based on quantal responses, the author first considers, in a general way, the various transformations which might be employed to produce a linear dosage-response relation, and then shows how the computations are carried out. The principles of good design are then discussed and found to be very similar to those for parallel line assays based upon quantitative responses. A chapter is devoted to a number of alternative but less exact methods which have been proposed in order to avoid the iterative calculations of the maximum likelihood solution. Then follows a chapter on some special problems with quantal responses; the treatment of estimates of the density of a bacterial suspension from a dilution series is particularly valuable. The work concludes with a short discussion of the use of time as a response. There are more than two hundred and fifty references, and seventeen useful tables for assisting computation.

In the subject of biological assay there are some matters which may still be considered controversial, or unsettled. Such points are the precise conditions under which limits of error can accurately be called 'fiducial', and under which the Fisher–Behrens distribution can be regarded as exact; the relative merits of the logistic and integrated normal distributions as conceptual models for tolerance distributions, and of maximum likelihood and minimum χ^2 solutions; the correct way of combining estimates from assays of different type; and the extent to which efficient but laborious methods of estimation can be replaced by methods less efficient but easier to calculate. When the author discusses these topics he is always fair.

In one of the early chapters a valuable distinction is made between *comparative* and *analytical* dilution assays. "In many assays the test preparation behaves as though it were simply a dilution (or a concentration) of the standard preparation in a diluent that is completely inert in respect of the response used . . . Assays in current use . . . are almost all either strictly or approximately *dilution assays*, to which category the theory and methods of this book are restricted. In some assays there may be strong reasons for believing that all constituents of the test preparation other than one are without effect on the response of the subjects. An assay of the preparation against a standard preparation of the effective constituent is then equivalent to an analysis for determining its content of the constituent: this may be described as an *analytical dilution assay*. In other circumstances the two preparations may for assay purposes behave as though qualitatively the same in effective constituents, though in fact they are not the same; the statistical methods appropriate to analytical assays may still be useful for arriving at convenient summaries of results, but such a *comparative dilution assay* is of more limited value as a basis of inference. . . .

"The results of such a *comparative dilution assay* need not have any validity under conditions other than those of its estimation. In an *analytical dilution assay* on the other hand the estimate of potency should be independent of the assay technique employed, and should agree with a process (perhaps chemical or physical) not using bioassay. The choice of subject, response, and experimental conditions should be irrelevant to the estimate that is formed, except in so far as they affect the precision of estimation."

The wide development of the technique of biological assay arose out of assays against international standards. There is a curious paradox here. Such assays are always intended to be *analytical assays*, but this is seldom completely true. With vitamin A, for example, the object is (or was) to determine the amount of vitamin A per gram in a preparation (say a cod-liver oil), but as the physical properties and chemical composition of vitamin A became known, the biological assay gradually became less and less necessary. To-day, vitamin A is, in fact, always assayed spectrophotometrically. The biological assay of digitalis is not strictly an analytical assay, for digitalis is a mixture of several different chemical compounds. When it becomes practicable to assay these separately biologically, it may well be unnecessary to do so. In general the more nearly a biological assay approaches to the ideal of an *analytical assay* the less necessary it becomes. When the ideal is reached the purpose of the assay is usually achieved. However, new biological standards are constantly being set up, so that the self-extinction of this branch of the subject, to use Sir Henry Dale's phrase, seems as far off as ever. Further, the number of possibilities for application of the technique of comparative dilution assays seems always to be increasing. So there is no fear of lack of new problems to which the fascinating statistical techniques, so ably described in this book, may be applied.

J. O. IRWIN

PHOTOELASTICITY AND ENGINEERING DESIGN

Designing by Photoelasticity

By Dr. R. B. Heywood. Pp. xvi+414+22 plates. (London: Chapman and Hall, Ltd., 1952.) 65*s*. net.

DR. HEYWOOD has drawn on the extensive experience of the photoelastic method of stress analysis he has gained while working in the Research Department of Rolls-Royce, Ltd., and in government service to present his views on "Designing by Photoelasticity".

The title of the book, suggesting as it does that one can design engineering components or structures by photoelasticity, may prove misleading to the uninitiated. Photoelasticity, like all the other methods of experimental stress analysis, is not a method of design; it is a method of analysis. It is not a creative but an analytical activity. Photoelastic stress analysis can only be carried out on a proposed design. Given such a design, photoelastic analysis can discover its weaknesses, and this information may or may not lead to a better design. The reviewer would wish to be the last person to belittle the importance of photoelasticity as an aid to design—it is probably the most powerful tool at present available for the determination of stress concentration factors—but no useful purpose is served by implying that it can do what it is inherently unfitted to do.

The author addresses his book both to photoelasticians and to engineers, and the book is divided into two parts. Part 1, which occupies about one-third of the length of the book, deals with some of the fundamentals of optics which are relevant to the photoelastic method of stress analysis, with the properties of photoelastic model materials, with the preparation of models and the necessary precautions which should be observed if models are to be loaded accurately, and with the validity of the transfer of information gained from a model made of a transparent plastic to a prototype of mild steel or light alloy. This section also deals with the 'frozen stress' technique used in the analysis of three-dimensional stress problems, giving a considerable amount of practical information.

Part 2 is devoted to the discussion of information derived from photoelastic data and from theoretical and empirical work by the author and others on stress concentrations caused by notches and holes. One chapter deals with stress concentrations in screw threads, bolts and nuts, while in another, improvements in the design of components are discussed which were obtained by paying attention to geometrical details, such as the radii of fillets, after the original design had been shown to be unsatisfactory by photoelastic investigations. The final chapter of the book is devoted to the application of stress concentration factors, their use in problems where fatigue is an important consideration and the effects of size on the applicability of these factors. The book is well illustrated and is completed by an extensive bibliography which, although it does not claim to be exhaustive, should prove most useful to workers in this field.

Some of Dr. Heywood's more dogmatic statements on photoelastic equipment and methods are not likely to meet with the agreement of all photoelasticians; but he undoubtedly deserves credit for collecting together within the confines of one book a great deal of information from a wide variety of scattered sources which should prove useful to engineering designers. E. K. Frankl

NATURAL HISTORY OF INFECTIOUS DISEASE

Natural History of Infectious Disease
By Sir Macfarlane Burnet. Second edition. Pp. x + 356. (Cambridge: At the University Press, 1953.) 22*s*. 6*d*. net.

The author of this book is not only himself a most distinguished research worker, but also he has perfected a method of presenting in a clear, palatable and most intelligible manner the natural history of infectious diseases. He treats them as a good naturalist should, when writing on his favourite subject, with regard to their place in Nature, their likes and preferences, methods of dissemination, their social background; in fact, all which may be termed, for a better word, their 'ecology'.

It is possible to regard the middle of the twentieth century as the end of the most important social revolution in history, the virtual elimination of infectious disease as a significant factor in human affairs. Could we be similarly assured of the abolition of war, we could feel confident of eternal peace and progress with the extinction of epidemics and a reduction of illness to mere trivialities.

Along with this has gone a steadily increasing interest in the morphology and characteristics of the responsible micro-organisms. Every animal species reproduces its kind at a far greater rate than is necessary to maintain its numbers.

Limiting factors are always present and the maintenance of a species can be regarded as the result of conflict between two opposing forces—what is known as the 'population pressure'. As an illustration the lesson of the introduced domestic mouse in Australia is cited. In certain years these creatures swarm in crops and haystacks, so that bucketfuls may be caught in a single night. Hawks, owls and cats gorge on them, while birds, like ibises, change their normal diet; and then, the plague ends suddenly. A few dead corpses litter the ground, and the numbers dwindle to below normal. Some infectious disease, such as *Streptobacillus moniliformis*, has been at work and has done what none of the predators could accomplish. How far can this lesson be applied to man? How comes it that all dwellers in insanitary cities do not die of infectious disease? New parasites creep in like the Black Death and spread from city to city with rats and fleas; syphilis sweeps through Europe with the advance of conquering armies, but cholera spreads invisibly from carriers, as it did a hundred years ago.

The evolution of infection and defence is a fascinating subject which takes us back to Metchnikoff, toiling in his laboratory with all kinds of outlandish creatures, while studying the cellular reactions and phagocytes in *Daphnia*, the water flea; and then the aggressors—bacteria and protozoa—all pass before our view. We can envisage some of the stages by which the complex life-history of the sleeping-sickness trypanosome came into being, by studying the simple life-story of closely related forms. There is one trypanosome, for example, which infects the blood of lizards and is derived from a small biting fly by the simple process of being swallowed.

The viruses are more complex and much light has been shed upon their habits and appearance by the electron microscope since the first pictures were taken by these means in 1938. The smallest particles are those of poliomyelitis. The study of viruses has also been amplified beyond computation by their cultivation on the amniotic cavity, the chorioallantoic membrane, the alimentary cavity and yolk sac of the domestic egg. It is explained, too, how much may be learned from contemplation of the many plant viruses which are of such great economic importance. This leads to a consideration of the rickettsiae, which form a step between the virus of psittacosis and the smaller members of the group.

The processes of defence are much more involved, but by this master-hand are made readily intelligible to intelligent minds. Finally, we are given an outline of the conquest of some important diseases, such as diphtheria, influenza, tuberculosis, plague, cholera and of the epic of malaria. Yellow fever, too, makes grand and sensational reading.

Enough has been said to show that this book makes a deep appeal to the ardent searcher after knowledge, as well as providing pleasant bedside-reading for the practising physician.

P. Manson-Bahr

Unto the Fields

By D. W. Gillingham. Pp. 286. (London: Museum Press, Ltd., 1953.) 17*s.* 6*d.* net.

Here, in this book, are the qualities—and how seldom they are found in conjunction—that go to the making of a good book about the English countryside; those qualities and some others. The author, as a child already sensitive both to beauty and cruelty, left a home in Leytonstone, while buttercups could still be gathered there, for Canada, where in boyhood his happiest years were spent. He returned nearly twenty years ago to much disillusionment. He has remained a Canadian in spirit, "with my roots left deep in the wide fellowship of the west". Yet, in spite of that loyalty and that disillusionment, he attributes to England "such beauty in her countryside as the rest of the world can but dream of".

Mr. Gillingham, it would seem, has devoted, since his return to that countryside, all his acute senses and most of his often scanty leisure to the development of a passionate sympathy, the more convincing by reason of a background of scientific knowledge and an awareness of history and pre-history, with the birds and beasts, the flowers and trees, the earth and the skies of a corner of Essex at the edge of London. He reports on the eve of war the advance of decay upon that beautiful place. He finds the more violent assaults of war-time upon it in some measure dignified by a sense of purpose. Returning from war service overseas, he recounts briefly and grimly its devastation by a London County Council housing estate.

Those who are capable of entering into so close and loving a communion with the earth and its creatures, as is here with a hundred vivid and delightful details recorded, are rare. Those who can also on the printed page bring alive to their fellows so passionate a sympathy are rarer yet. Mr. Gillingham combines the accurate observation and recording of things seen and heard with an imaginative outlook and a handsome command of the English tongue. An unusual and a rewarding book, well illustrated by Mr. Henry Pettit. STEPHEN TALLENTS

Annual Review of Biochemistry

J. Murray Luck (editor), Hubert S. Loring and Gordon Mackinney (associate editors). Vol. 20. Pp. x+648. Vol. 21. Pp. x+781. (Stanford, Calif.: Annual Reviews, Inc., 1952.) 6 dollars each.

The "Annual Review of Biochemistry" was the first of many hardy annuals, and is now entering its third decennium. The editorial committee points out that it began with considerable confidence in the belief that the reviews would be critically written, but that sometimes unexpectedly a review, as received from the author, proves to be an assortment of abstracts, brief, terse and numerous—the result of a valiant effort to treat the literature comprehensively rather than selectively.

In the reviewer's opinion the majority of the articles in the two volumes under consideration are reasonably selective and are at the level of usefulness to be expected from the critical equipment of each individual author; but naturally there is variation from one article to another. Among subjects which do not qualify for annual review are "Biochemical Genetics", by N. H. Horowitz and H. K. Mitchell, and "The Metabolism of Drugs and Toxic Substances", by R. T. Williams; and "Chromatography", by S. Moore and W. H. Stein. The latter in particular is a valuable and critical appraisal of a field that is growing at once in importance and complexity.

"Biological Oxidations" is a subject considered annually and is usually given first place, as being of fundamental importance; though the lucid and authoritative review of this subject by Britton Chance and L. Smith in Vol. 21 is the last article in the book, this position may result not from a new attitude to the subject but from accidental causes.

The production is good and the indexes are excellent. The standard we have learned to expect from "Annual Reviews" is clearly maintained. F. G. YOUNG

Many-valued Logics

By Prof. J. Barkley Rosser and Prof. Atwell R. Turquette. (Studies in Logic and the Foundations of Mathematics.) Pp. vii+124. (Amsterdam: North-Holland Publishing Co., 1952.) 12 fl.

This manual forms a most distinguished contribution to the literature and development of many-valued logic. As such, its appeal must be mainly to the specialists, and to those whose interests lie in the formal structure of mathematical thought. Consequently, most of the space available is devoted to the necessary extension of truth tables, axiomatization, and quantification for particular predicate calculi.

In the present context, however, the authors' aim —stated quite simply—is to see what happens when the possibility is admitted that a given situation may be other than true or false. This concept is introduced by a delightful dialogue in which the two authors split up and re-unite their names, one (Turquer) arguing for the *status quo*, and the other (Rossette) for adventure. The result, of course, is a foregone conclusion, as otherwise the book would never have been written. Adventure wins, and, heartened by the historic triumphs of non-Euclidean geometries, a start is made.

An intriguing section deals with some unanswered questions, and the probability of increased complexity when decision-problems have to be tackled in many-valued logics. The authors might well have mentioned the use which theoretical physicists are beginning to make—in fact, may be compelled to make—of many-valued systems in some of their crucial concepts. For all these reasons, this little book is likely to become a classic in its own right.

F. I. G. RAWLINS

Dartmoor

By L. A. Harvey and D. St. Leger-Gordon. (The New Naturalist Series: a Survey of British Natural History.) Pp. xiv+273+40 plates. (London: William Collins, Sons and Co., Ltd., 1953.) 25*s.* net.

This recent addition to the New Naturalist Series will appeal to many readers because of the intrinsic interest and appeal of the region described, and the very readable way in which the authors have presented their subject. In particular, scientific readers will appreciate the thoroughness of treatment and, not least, the cautious reserve that permeates the text. Dartmoor is described and discussed in the text in terms of its value as a national park, its physical pattern, geology and climate, its moors, tors, bogs and woodlands, its rivers and pools, its flora, fauna, prehistory, history and the customs and outlook of its contemporary denizens. Some valuable floristic and faunistic lists are given, and the volume is attractively illustrated throughout.

THE FLOW OF GLACIERS*

By Dr. M. F. PERUTZ
Cavendish Laboratory, Cambridge

Introduction

GLACIERS are fed by the snowfields which flank the high mountains. Snow deposited there is transformed into ice in the course of five to ten years. The ice flows down to the valley, where it gradually melts away until nothing is left but the rubble which the glacier carried down with it from the heights, piled up in an ungainly moraine.

In summer, a horizontal line can be seen dividing glaciers into two distinct regions: the upper one which is permanently covered with snow, because the summer's heat never suffices to melt away the snow deposited in the preceding winter, and the lower one in which the bare ice is exposed because melting and evaporation are dominant. In a glacier at equilibrium the amount of snow deposited is balanced by the water removed, and the size of the glacier remains unchanged. For the past fifty years the glaciers have lived on the reserves accumulated during the rich snowfalls of the Victorian era, and some have now shrunk to mere shadows of their former selves.

There are many kinds of glaciers. Some are scarcely more than snow patches and flow only a few feet a year. The valley glaciers of the Alps, of which the Mer de Glace is the best known, and the most visited, flow with velocities of one, two or three hundred feet a year. The gigantic ice streams of Greenland and Alaska which terminate in the sea flow much faster. The record is held by the Umanak Glacier in Greenland, which attains an annual velocity of several miles.

Ice is apparently rigid and brittle, yet glaciers flow like streams of a very viscous liquid. The streaming motion can be observed by watching the gradual distortion of certain pressure waves which form at the foot of ice-falls. When they first form, these waves skirt the ice-fall in a slightly curved line; as it flows down the glacier, each line is gradually drawn out into a parabolic curve pointing valleywards, which shows that the ice flows faster in the centre of the glacier than at the sides, like water in a river.

Theories of Flow

The flow of glaciers has always puzzled men of science, and until recently glaciological literature has been a battlefield of contradictory theories. The theories can best be explained by considering the fate of a rubber tube extending vertically from the surface to the bed of a glacier (Fig. 1). Somigliana regarded ice as a liquid of constant viscosity, which implied that its rate of flow would be directly proportional to the stress. The rubber tube would be deformed into a parabola, with the velocity of flow at the bed approaching zero. This theory clearly fails to explain glacial erosion. Orowan proposed the fruitful idea that ice behaves as an ideal plastic solid: substances of this type are assumed to be infinitely rigid until a certain limiting stress is reached; they then give way with infinite ease. If ice were ideally plastic, the depth of glaciers would have to be such that the limiting stress is reached at the bed, where all flow would be concentrated. Orowan's ideas formed the starting point for Nye's important theoretical advances to which I shall refer later in my lecture. Chamberlin and Philip fixed their attention on certain internal thrust planes which they believed to be of crucial importance, while Streiff-Becker and Demorest proposed a fast-flowing layer in the centre of the glacier, an idea which gained widespread adherence despite its mechanically improbable nature.

None of these theories could form the basis for any real advance in our knowledge so long as there existed no experiments either to confirm or disprove them. This state of affairs stimulated a group of people to try to discover the physical laws governing the flow of ice and the molecular mechanism on which these laws are based; to apply these laws to the flow of glaciers and to test them by direct measurement of the velocity distribution inside them. In Great Britain, the most active members of this group have been G. Seligman, president of the Glaciological Society, W. V. Lewis, E. Orowan, J. McCall, J. F. Nye, J. W. Glen and myself. Many others have made important contributions.

Deformation of Ice Crystals

The water molecules in an ice crystal are arranged in a succession of parallel layers, each layer consisting of a honeycomb of puckered hexagonal sheets. In a large ice crystal a misfit, usually called a dislocation, sometimes weakens the cohesion between two neighbouring layers, and when a stress is applied to the crystal the two layers glide over each other. Steinemann has found indications that such dislocations occur at intervals of 10–20 million layers.

Glen[1] made a rod-shaped ice crystal with the layers at 45° to the length of the rod and clamped it in an

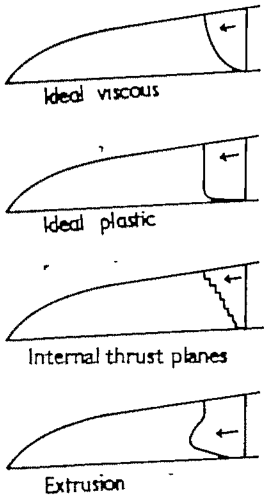

Fig. 1. Velocity distribution along a vertical line through a glacier according to different theories of flow

* Substance of a Friday Evening Discourse at the Royal Institution, delivered on June 5.

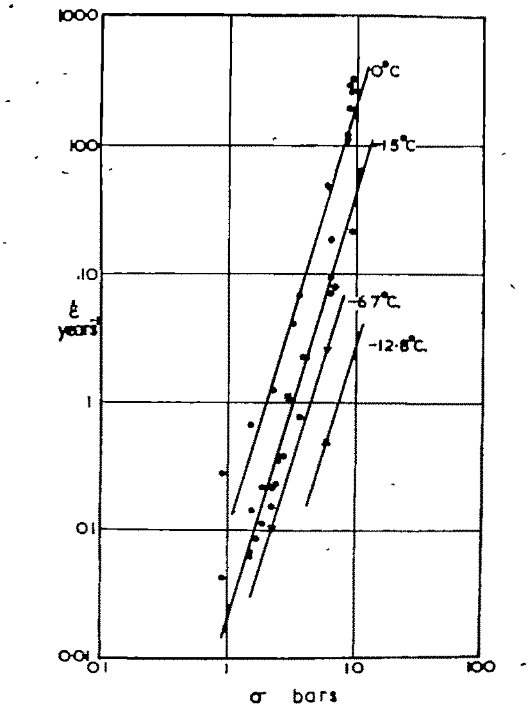

Fig. 2. Plot of logarithm of minimum rate of creep of ice against logarithm of stress. ●, points from creep tests very close to the melting point; ○, points from tests at − 1·5° C.; ◇, points from tests at − 1·5° C. after increasing the stress; □ points from tests at − 1·5° C. after decreasing the stress; ▼, points from tests at − 6·7° C.; △, point from test at − 12·8° C.

extension machine. When a small continuous pull was exerted on the rod it stretched to a thin tape of many times its original length. This shows that a single crystal of ice can be deformed plastically by continuous application of a small stress (of the order of a few kgm./cm.^{2}), although it suffers brittle fracture when a large stress is suddenly applied.
